Abstract

Titanium-indium (oxy)nitride composite materials with and without RuO$_2$ loadings were produced by treating TiO$_2$-In$_2$O$_3$ mixed powders with ammonia at high temperature (700-850 °C) (Elemental analysis indicated an empirical formula of TiIn$_{0.029}$O$_{0.63}$N$_{1.4}$).

We have found that ammonolysis of TiO$_2$ to form Ti (oxy)nitride or In$_2$O$_3$ to form In (oxy)nitride do not give composites active toward methanol-water under visible light, but TiO$_2$ and In$_2$O$_3$ mixed together do give composites active toward methanol-water under visible light. Ti-In (oxy)nitride powders modified by surface loading with RuO$_2$ nanoparticles at 3 wt % achieves the highest H$_2$ evolution activity under visible light irradiation. The composite material did not react in the dark, but upon irradiation with visible light, the hydrogen production rate under illumination goes way up to 30 μmole·h$^{-1}$ and the turnover number shows that this is a photocatalytic reaction.

Graphical abstract

Photocatalytic H$_2$ evolution test
Highlights

► Titanium-Indium Oxy(nitride) with and without RuO$_2$ loading as Photocatalysts were investigated. ► 3 wt% RuO$_2$-loaded Ti-In oxy(nitride) composites showed higher catalytic performance than the other photocatalysts. ► The XPS data shows Ti$^{4+}$ could be reduced to 3+ and 2+ upon ammonia treatment with In$_2$O$_3$ presence. ► It was found that the treatment temperature increased from 750 to 850 °C, the composites began to aggregate because of growth of the TiO$_2$ (anatase).

1. Introduction
Osterloh[1] has recently reviewed inorganic materials for photochemical water splitting. Over 130 inorganic materials/composites are mentioned. Metal nitrides and metal-oxynitride composites have also received some study, such as $\beta$-Ge$_3$N$_4$ and GaN:ZnO solid solution prepared from commercially available GeO$_2$ powder or a mixture of Ga$_2$O$_3$ and ZnO by nitridation under atmospheric NH$_3$ flow, respectively, and loaded with RuO$_2$ as co-catalyst.[2, 3] These studies revealed that the photocatalytic activity for water splitting depends on the crystallinity and composition of the material. Moreover, evidence shows that using nitrogen to replace Oxygen in TiO$_2$ to form TiO$_2$-$_x$N$_x$ can enhance photocatalytic activities under visible light.[4, 5]

Additionally, Poznyak and co-workers have investigated the photoelectrochemical properties of nanocrystalline TiO$_2$/In$_2$O$_3$ composite solids.[6] It was shown that TiO$_2$/In$_2$O$_3$ composites allow efficient separation of photogenerated charge carriers occurring in interconnected TiO$_2$ and In$_2$O$_3$ particles, owing to the favorable energetics of the conduction bands of these oxides. Another report shows that nitrogen-doped In$_2$O$_3$ thin film electrodes are effective for photocatalytic water splitting.[7] Therefore, it may be possible to combine the TiO$_2$ property of formation of electrons and holes by absorbing light and then using the interconnection between TiO$_2$ and In$_2$O$_3$ to transfer the holes to In$_2$O$_3$. Moreover, the nitrided treatment of a mixture of titanium oxide and indium oxide may be effective to enhance absorption of visible light. In our research, optimal preparation conditions were investigated in order to achieve the best hydrogen production under visible light. Reported herein are our results with methanol-water solutions.
2. Experimental

2.1. Preparation of Ti-In nitride composites with and without RuO$_2$

Composite powders were prepared by heating a mixture of 0.92 g ($1.2 \times 10^{-2}$ mol) anatase TiO$_2$ powder (Sigma-Aldrich, anatase, nanopowder, <25nm, 99.7%) and 3.2 g ($1.2 \times 10^{-2}$ mol) In$_2$O$_3$ powder (Sigma-Aldrich, nanopowder, <100nm, 99.9%) at different temperatures under NH$_3$ flow (250 mL/min) for 20 hours as shown in Fig. 1 (The reaction chamber diameter is 4.5 cm). The mole ratio of Ti to In in the starting material (TiO$_2$ and In$_2$O$_3$) was 1/1, which should give a Ti:In ratio of 1:2 (although, in reality, much of the indium was lost during the ammonia treatment; see later discussion). After 20 hours of ammonolysis, the sample was cooled to room temperature under NH$_3$ flow.

Fig. 1. Experimental setup for nitridation of TiO$_2$/In$_2$O$_3$ mixture.
RuO$_2$ was loaded onto the as-prepared Ti-In nitride powders as a co-catalyst by immersing the Ti-In nitride composite powders in a tetrahydrofuran (THF) solution containing dissolved ruthenium(III) acetylacetonate (purum, $\geq 97.0\%$ (CH), Fluka) and stirring. The solution was then dried under air by heating in air at 80 °C to remove THF. The obtained powders were finally annealed in air at 400 °C for 4 h.

2.2 Photocatalytic activity

The reactions were carried out in a glass-enclosed reaction chamber connected to a gas circulation and evacuation system with a quartz inner irradiation-type reaction vessel.[8] The apparatus contained 345 ml 10 vol% methanol-water solution with 0.13 g sulfuric acid and 0.30 g of the composite RuO$_2$-loaded Ti-In (oxy)nitride. The reactant solution was evacuated and filled with argon three times to remove air completely, followed by irradiation ($\lambda > 400$ nm) under a 450 W high-pressure Hg lamp via a quartz tube that was air filled for full spectrum UV-vis studies, or filled with 2 M NaNO$_2$ aqueous solution for visible light studies.[3] The reaction temperature was controlled between 20 to 25 °C. H$_2$ production was monitored during the reaction with an online GC system (GOMAC model) employing a Supelco molecular 80/100 sieve 5A column with Ar as the carrier gas and a thermal conductivity detector (TCD).

2.3. Characterization of composites

The prepared samples were studied by powder X-ray diffraction (XRD; Bruker D8 X-ray diffractometer with Cu K$\alpha$ radiation), scanning electron microscopy (SEM; Hitachi S-3500 N), UV-visible diffuse reflectance spectroscopy (DRS; Varian Cary 500 Scan).
The Brunauer, Emmett, Teller (BET) surface area was measured with a Quantachrome NOVA-1200 instrument at liquid nitrogen temperature. X-ray photoelectron spectroscopy (XPS) was conducted using a SPECS Sage100 spectrometer operating in the fixed analyzer transmission mode using achromatic Mg Kα (1253.6 eV) radiation at 240 W (12 kV and 20 mA) using a water-cooled X-ray gun cap and evacuated with turbomolecular pumping. The base pressure of the chamber was about $2 \times 10^{-8}$ Torr, and the energy scales were calibrated using copper and the separation between photoelectron peaks generated by Mg and Al Kα X-rays. Survey spectra were collected with a pass energy of 30 eV; a pass energy of 15 eV was used for both core and valence band spectra. Many of the spectra were calibrated by taking the C 1s peak due to residual hydrocarbon as being at 284.4 eV.

3. Results and Discussion

3.1. Characterization of Ti-In oxy(nitride) composites

Fig. 2 shows XRD patterns from samples obtained by nitriding a mixture of TiO$_2$ and In$_2$O$_3$ at several ammonolysis temperatures. TiO$_2$, In$_2$O$_3$ and TiN data are shown for comparison. All composites’ patterns are similar to TiN and the peak assignments are based on the ICSD database. None of the diffraction peaks of starting materials were observed, indicating that the obtained samples were not physical mixtures of TiO$_2$ and In$_2$O$_3$. The peak around 34° corresponds to both InN and In metal. The XRD data demonstrate that an ammonolysis temperature above 850 °C, caused an increase of In metal formation (which was generally lost due to the volatility). It is known that In$_2$O$_3$ is
reduced to metallic Indium upon ammonolysis of Indium oxide by anhydrous ammonia.

*Fig. 2. Powder XRD patterns of Ti-In oxy(nitride) composites obtained by different ammonolysis temperatures samples. (c) 700 °C (d) 750 °C (e) 800 °C (f) 850 °C. *(a) TiO$_2$ anatase (b) In$_2$O$_3$ (g) TiN for comparsion.*

above 650 °C.[9] Indeed, we found that starting with only In$_2$O$_3$ and then nitridation, indium metal was produced under the action of hot NH$_3$. The high ammonolysis temperature not only reduced In$^{3+}$ into In, but also could cause InN decomposition. Decomposition temperatures reported for InN range from 500 °C for thin films[10, 11] to 710 °C. In our research, even when the ammonolysis temperature was above 700 °C,
some InN persisted when TiO$_2$ was also present as a co-reactant. Therefore, combining TiO$_2$ and In$_2$O$_3$ not only created H$_2$ production activity, but also helped to stabilize InN.

We have examined four areas of the XPS spectra for several samples: the Ti 2p region (466-453 eV), In 3d region (450-454 eV), the O 1s region (525-537 eV), and the N 1s region (394-400 eV). The survey spectra of all the Ti-In (oxy)nitride powders confirmed the presence of Ti, In, O, N and C. The binding energies (BEs) were calibrated using the C 1s energy of 284.4 eV as an internal calibration.

The Ti 2p$_{1/2}$ has three peaks (Fig. 3A), 458.5 eV, 457 eV and 455.6 eV. Ti 2p$_{3/2}$ has three peaks, 463.9 eV, 462.5 eV and 461.3 eV. They are in agreement with the values reported in the literature for Ti$^{4+}$, Ti$^{3+}$ and Ti$^{2+}$, respectively.[9, 12] The XPS data show that the ammonolysis process can reduce Ti$^{4+}$ to lower oxidation states. Moreover, the low ammonolysis temperature samples have a higher ratio of Ti$^{4+}$, which shows the higher ammonia treatment temperature causes more reduction of Ti$^{4+}$ into Ti$^{3+}$ or Ti$^{2+}$. One interesting finding was that there was no Ti$^{3+}$ and Ti$^{2+}$ formation when only TiO$_2$ was nitrided by hot NH$_3$. This again, suggests that there is an important synergistic interaction between In and Ti during the nitridation.

As shown in Fig. 3B, The In core spin orbit split to the 3d$_{5/2}$ peak at 444.5 eV. These results are close to the reported values for bulk InN (444.3 eV). [7, 13] Therefore, XPS further confirms the formation of InN.

Regarding the XPS spectra after photocatalytic reaction, In 3d$_{3/2}$ XPS spectra (Fig. 3) shows loss of intensity for low ammonolysis temperature samples, which suggests that the lower temperatures yield less stable nitrides. But if the ammonolysis temperature exceeds 850°C, most of the In was sublimed and lost, and only TiN remained. The
Fig. 3. XPS spectra of Ti-In oxy(nitride) composites obtained by different ammonolysis temperatures. (a) 850 °C (b) 800 °C (c) 750 °C (d) 700 °C.

resulting sample had poor H₂ production activity. Therefore, a suitable ammonolysis temperature is very important, which has to be high enough to allow N doping, but not too high to further reduce In³⁺ into In metal. All In 3d₃/₂ XPS spectra (Fig. 3) show the shifting to higher BE after the reaction, which indicates that some of the doped nitrogen was replaced by oxygen.

Fig. 3C shows that the O 1s core level is composed of at least three components. The peak positions and intensities are reliably determined by a standard curve fitting procedure using XPSPEAKS software. The O 1s signal at 529.8 eV is assigned to In₂O₃.
and TiO$_2$ according to the literature,[14] while the signal at 530.8 eV is probably due to oxygen in surface adsorbed hydroxyl groups[15] and the signal at 532.1 eV is from the surface adsorbed H$_2$O. Low ammonolysis temperature samples show a small shift to lower energy (529.0 eV) for the O 1s peak that is assigned to In$_2$O$_3$ and TiO$_2$. This shift is similar to results found for substitutional N-doped TiO$_2$ samples, in which the P25 TiO$_2$ sample shows an O 1s peak at 530.8 eV, versus a shift to 530.0 eV that is observed for the nitrogen-doped TiO$_2$ samples.[16]

The N 1s XPS spectrum in Fig. 3D has two components: 396.9 eV and 396.2 eV. The N 1s XPS data confirms the N is substitutional instead of interstitial. [4, 5, 17] The 396.9 eV peak could be assigned to Ti-N, and In-N is at 396.2 eV because Ti has a higher electronegativity than In. The XPS high-resolution spectra of N 1s show the 850 °C ammonolysis sample’s peak at 396.7 eV with a slight shift to 396.1 eV for the 700 °C sample (Fig. 3D). The difference of 0.6 eV between these two N 1s peaks correlates with InN formation for the N 1s state in substitutional sites. Therefore, the data (Fig. 3D) shows more formation of N in substitutional sites under higher ammonolysis temperature conditions.

### 3.2. Photocatalytic activity of Ti-In oxy(nitride) composites

Fig. 4 shows the hydrogen production activity of a Ti-In oxy(nitride) composite (ammonolysis at 700 °C) in 10 vol% methanol-water solution under visible light. In the dark, there was no activity observed. However, after the light was on, the reaction can be driven by visible light, producing ~0.5 µmole·h$^{-1}$ H$_2$ gas. The activity stabilized, and
continued to produce H$_2$ gas for over 200 hours. H$_2$SO$_4$ was added to adjust solution pH to acidic condition, the photocatalytic activity was not enhanced.

![Graph of H$_2$ Gas evolution vs Reaction Time (hours)](image)

**Fig. 4.** Dependence of visible light hydrogen production activity of a Ti-In oxy(nitride) composite (ammonolysis at 700 °C) without RuO$_2$. Catalyst (0.3g), an 10 vol% methanol-water solution; light source, high-pressure mercury lamp (450 W) with 2M NaNO$_2$ solution as a filtration. Inner irradiation-type reaction vessel. Reaction temperature was controlled between 20 to 25 °C.

### 3.3. Photocatalytic activity of RuO$_2$-loaded Ti-In oxy(nitride) composites

Ti-In oxy(nitride) composites alone exhibited only small photocatalytic activity for hydrogen evolution. However, when loaded with RuO$_2$, the material became much more photocatalytically active. Fig. 5 shows the dependence of visible light activity of different ammonolysis temperatures RuO$_2$-loaded (1 wt%) Ti-In (oxy)nitride samples in pH adjusted (sulfuric acid) 10 vol% methanol-water solution. (In this work, methanol is used
as a sacrificial agent so that the best condition for the hydrogen evolution step can be ascertained.[18]) The hydrogen production activity was observed at a higher rate. The light source was turned off after 5 h (Fig. 5), and no hydrogen evolution activity was

![Graph](image1)

**Fig. 5.** Dependence of visible light hydrogen production activity of RuO$_2$-loaded (1 wt %) Ti-In oxy(nitride) composites obtained by different ammonolysis temperatures samples. Catalyst (0.3g), an methanol-water solution (10 vol %); light source, high-pressure mercury lamp (450 W) with 2M NaNO$_2$ solution as a UV light filter. Inner irradiation-type reaction vessel. noted, indicating that this is a photo-driven reaction. Moreover, the maximum rate of H$_2$ evolution was 14 μmole·h$^{-1}$. The amount of the RuO$_2$-loaded Ti-In oxy(nitride) photocatalyst used contained 22 μmol of RuO$_2$. The number of electrons consumed was estimated to be 516 μmol judging from the amount of evolved H$_2$. The electron turnover number to amounts of loaded RuO$_2$ reached 23, respectively, after 45 h of irradiation. Therefore, by this measure it can be concluded that H$_2$ evolution photocatalytically proceeded.
Fig. 6. SEM images of RuO$_2$-loaded (1 wt%) Ti-In oxy(nitride) composites obtained by different ammonolysis temperatures. (a) 700 °C (b) 750 °C (c) 800 °C (d) 850 °C.

The surface morphologies of RuO$_2$-loaded Ti-In oxy(nitride) composites are presented in Fig. 6. The average particle size of the individual units of the sample treated at 700 °C was about 20 nm (Fig. 7). However, as the treatment temperature increased from 750 to 850 °C, the units began to aggregate and the boundaries between them became increasingly unclear because of growth of the TiO$_2$ (anatase) (Fig. 8, inset).

absorbance in the visible region along with the increase of RuO₂ loading. Based on UV-Visible spectra, the hydrogen production is affected by visible light absorbance: the higher the absorbance, the higher the activity. The decrease in photocatalytic activity with higher RuO₂ content indicates that loading with excess RuO₂ causes agglomeration and reduces the number density of photocatalytic active sites. Fig. 10 shows the SEM and

TEM images of the RuO₂-loaded Ti-In oxy(nitride) composites. The surface morphology shows no obvious change during the increase of loaded RuO₂. However, TEM images show more dark dots inside the particles due to the agglomeration of excess RuO₂. The same tendency has been reported for RuO₂-loaded (Ga_{1-x}Zn_{x})(N_{1-x}O_x) solid solution[19] and (Zn_{1-x}Ge)(N_{2}O_x) Solid Solution[20]. Moreover, the decrease of surface area may due to the agglomeration (Table 2), when the RuO₂ loaded amount exceeds 3 wt%.

During these experiments there was no O$_2$ evolution observed, even though the potential of generated holes might be thermodynamically high enough for oxidation of water to form O$_2$. However, there are no reaction centers for the four-electron oxidation for O$_2$ evolution. On the other hand, the standard redox potentials for HCHO/CH$_3$OH and H$_2$CO$_3$/CH$_3$OH are 0.232 and 0.044 V, so methanol oxidation is easy compared to oxidation of water coupled with O$_2$ evolution from water (1.23 V) from both thermodynamic and kinetic standpoints.[21] Moreover, it is well-known that O$_2$ evolution has a large overpotential (> 0.5 V).[21]

4. Conclusions

Novel RuO$_2$-loaded Ti-In (oxy)nitride composites were prepared by nitridation of TiO$_2$ and In$_2$O$_3$ under an NH$_3$ flow of 250 mL·min$^{-1}$ and loaded with RuO$_2$ by using Ruthenium(III) acetylacetonate as the precursor. The preparation of (oxy)nitride provides a new strategy to synthesize InN at high temperature (> 700 °C). And Ti$^{4+}$ could be reduced to 3+ and 2+ upon ammonia treatment with In$_2$O$_3$ presence. The change in the
product with nitridation temperature was examined, and it was revealed that an active mixed nitride/oxide phase formed above 700 °C of nitridation. However, temperature above 900 °C caused Indium metal to form, which is volatile at 900 °C and was lost, resulting in mainly TiN formation, and these samples exhibited no photocatalytic activity. The XRD and XPS spectra confirmed that the prepared powders had nitrogen substituted at some of the oxygen sites in the TiO$_2$ and In$_2$O$_3$. The UV-Visible diffuse reflectance spectra absorbance in the visible light region varied with RuO$_2$ loaded amount from 1 to 4 wt%, which are directly reflected by different H$_2$ evolution activities, but excess RuO$_2$ may reduce the number density of photocatalytic active sites resulting a lower performance. The optimum preparation conditions for RuO$_2$-loaded Ti-In (oxy)nitride in order to achieve high hydrogen evolution are thus considered to be nitridation between 700 to 850 °C under NH$_3$ flow at 250 mL·min$^{-1}$ and loaded with 3 wt% RuO$_2$. The composite produced under these conditions minimizes Indium loss by reduction to Indium metal and subsequent volatilization, but some Indium is retained as InN that is stabilized in the structure, and is important in hydrogen production. And the 3 wt% RuO$_2$ loaded amount gave the optimum balance between reaction sites and aggregation.
