1. INTRODUCTION

Communication protocols¹ are widely used in computer-to-computer information transmission for routing, error detection and flow control. Many protocols (computer and non-computer) have been proposed over the past several decades. The earliest technical protocols dealt with telegraph-like communication [Fah74]; early hardware was typically used to send "messages" to a receiver via a series of shocks, since the light bulb and electromagnetic relay were invented years after these original protocols. Later techniques used magnetically-operated levers and signals to send letters and numerals using some ingenious and compact methods². Protocols proposed over the last several years have steadily increased in complexity to better use the available communication media and to handle an increasing volume of information.

This work reports on an existing basic communications protocol and then extends that protocol with previously published mechanisms [Tan81, Bla83, Dav83]. The analysis of the extended protocol and its implementation in a concurrent language environment (Concurrent C) are also described. The environment also provides an interface for testing this and other protocol implementations within a limited architecture. Several scenarios are presented to show that the enhanced protocol recovers properly from "seeded" errors.

The work has application in the areas of interprocessor communication and data transmission. Since the protocol provides "reliable" node-to-node transmission of data, it is possible to use it as part of a reliable terminal-to-mainframe communication protocol. The

1. Protocols are the rules and conventions used to communicate between entities or processes.

2. One such protocol's summary ended "With such an apparatus no errors could possibly occur, for everything went like clockwork." [Amy38] Others believed "...success...would likewise depend no on an apparatus liable to an infinite number of accidents, scarce in the power of human foresight to guard against." [Gam97] Protocol designers should keep the latter comment in mind.

concurrent-language test-bed offers a mechanism to test new protocol implementations at the "user" level without the need to create a new test environment.

Chapter 2 summarizes a portion of the abundant literature on communication problems and protocol analysis and design. The basic protocol mentioned above is also described in some detail. In Chapter 3, some possible extensions to the basic protocol are presented. Some of these extensions are then integrated into the basic protocol, and an analysis of the enhanced protocol is presented. Chapter 4 offers a concurrent language implementation of the enhanced protocol together with a test generator/monitor. The conclusions in Chapter 5 also present some areas for further investigation and discuss other implementation possibilities.

2. EXISTING LITERATURE

Communication protocols and their analysis have been a topic of a large volume of literature, both in book and journal form. Unfortunately, much of the design and implementation of protocols was originally performed by equipment manufacturers, with the usual results: Each manufacturer used a private protocol, incompatible with all others. Eventually, the major manufacturers' (primarily IBM and Digital Equipment) protocols became *de facto* standards. The literature reflected this proliferation of standards by using inconsistent and ambiguous terminology. Attempting to define a "common ground" for discussion, several standards organizations together created an architectural model for communication processes. The result is called the Reference Model of Open Systems Interconnection (hereafter called the OSI Model), sponsored by the International Standards Organization. [Zim80]

2.1 OSI Model

To place the protocols mentioned below into their proper perspective relative to the overall process of communication, the OSI Model will first be summarized. The OSI Model architecture partitions communication into seven layers. Within an entity (also called a *node*), each numbered layer "interfaces" functionally only with its adjacent layers by providing services to the layer above and using services of the layer below. Communication between entities logically takes place only between like-numbered layers using a protocol for that layer. These protocols operate using the services provided by the next lower layer. The defined layers and their numbers are:

Application Layer (7) - provides support directly to the Application Processes executing across the various communicating entities (for example, process synchronization).

Presentation Layer (6) - provides data transformations between Application Processes (e.g., compaction/expansion).

Session Layer (5) - provides the "dialogue" connection between pairs of Application Processes (via Level 6) and the capability to establish the connection.

Transport Layer (4) - provides reliable end-to-end transmission of messages between communicating processes.

Network Layer (3) - provides the means for sending messages between any pair of entities within the network, typically providing routing and flow control on an end-to-end basis.

Link Layer (2) - provides the means to reliably exchange sequences of messages between directly-connected entities.

Physical Layer (1) - provides the electrical and mechanical connection between entities and services to the Link layer allowing message transmission.

Typically, a message from a higher-numbered layer is transported by prefixing a layer "header" to the message and sending the message to the next lower layer. Message reception operates in the reverse order; receiving messages from the lower layer, removing and processing the layer "header" and delivering the remaining portion of the message to the next higher layer.

2.2 Link Layer

This paper will be primarily concerned with protocols at the Link layer (Layer 3). Thus issues such as physical media (Layer 1) and routing (Layer 3) will not be covered. To provide services to the Network layer as mentioned above, the Link layer must be able to:

1. identify or address the required physical unit for transmission,
2. maintain a logical sequence of messages for each logical data link,
3. handle errors in message ordering and transmission and
4. control the flow of messages on the physical connection.

These capabilities are provided by "framing" the messages into blocks that have a structure determined by the protocol. The Link layer sends and receives these *frames*³ through

services provided by the Physical layer. The Physical layer's primary service is the transmission of bit or character streams over a logical link.

The Link layer of a particular network topology is influenced by that topology, even though routing through the network is not a function of this layer. This is because connections other than *node-to-node* (i.e., between directly connected entities) are supported by the OSI Model. These other connections are termed *multipoint*; this type of Link layer connection is not covered in this paper. Node-to-node connections at the Link layer are "logical links" in that one real transmission path may support several logically distinct connections between the same pair of nodes. The interface between the Link layer and the Physical layer would, in this case, require a logical link identification on every exchange of information to maintain the logical link association. Within the node-to-node type of connection, two methods of "framing" the messages are commonly used. One of these is known as *character-oriented*; the other is called *bit-oriented*.

The bit-oriented protocols are newer and have several advantages over the character-oriented protocols. The basic unit in the frame is a bit; certain bit sequences are used to detect the beginning and ends of frames. The frame can typically contain any number of bits. These protocols are inherently transparent to character set size and codes through the use of a technique called "bit-stuffing." (This replaces certain bit sequences with other sequences that have extra zero bits within them, thus preventing the framing bit sequences from appearing within the unit sent to the Physical layer.) The bit-manipulation required (monitoring for

3. The term *frame* is used in this chapter to refer to data units exchanged between nodes at the Link layer. The OSI Model's corresponding term is "physical-layer-service-data-unit," but one suspects this is somewhat shortened in informal conversation.

special bit sequences and shifting to add or delete the extra zero bits) almost forces the Link layer (or a portion of it) into hardware; the overhead on general-purpose computers would overcome most of the advantages. Some examples of bit-oriented protocols are:

- HDLC (High Level Data Link Control) - part of ISO X.25,
- ADCCP (Advanced Data Communication Control Protocol) - ANSI,
- SDLC (Synchronous Data Link Control) - part of SNA from IBM,
- BDLC (Burroughs Data Link Control) - Burroughs and
- UDLC (Univac Data Link Control) - Univac.

2.3 Character-oriented protocols

Character-oriented protocols are based on characters as the unit of transmission. Typically, a small set of seldom-occurring characters are chosen as "control" characters. The occurrence of these characters in the input is used to delimit and define the frame sent between nodes at the Link layer. The following functions are basic [Con80] to character-oriented Link layer protocols:

1. *Framing* places a structure on the character stream received from the Physical layer by identifying the beginning and end of frames.
2. *Error Detection* provides a means to determine if frames were altered in transmission. It also provides for detection of out-of-order frames.
3. *Recovery* controls the actions taken to recover from errors and lack of response from the connecting node.
4. *Flow Control* handles the rate of character flow between nodes.
5. *Link Control* allows the connection between nodes to be established and terminated.

Each function will be described in some detail below, except for *Flow Control*, which is typically handled by ignoring frames that the node is not prepared to receive. Also, a *Transparency* function is provided by many character-oriented Link layer protocols; this allows "control" character bit sequences to be sent as data without being considered "control" characters by the *Framing* function.

Framing is accomplished by using a particular "control" character to identify the beginning of a frame. The end of the frame is identified either by a different "control" character or by a character count contained within the frame. (The latter method is usually called a *byte-count character-oriented* protocol.) The *Framing* function scans the incoming characters from the Physical layer for the beginning-of-frame character. Everything after that until an end-of-frame character (or the number of characters in the character-count) is considered a frame.

Error Detection of transmission-induced alterations to the frame is commonly performed by *checksums*. A checksum is the result of a computation over the characters in the frame. The checksum is sent with the frame; on receipt, the checksum computation is performed again and compared to the transmitted checksum. The frame is considered "damaged" if the two checksums are not equal⁴. The most commonly known checksum methods are:

ARPANET Internet - "...the 16-bit one's complement of the one's complement sum of the 16-bit of all 16-bit words..." [Pos81],

CRC-16 - the remainder after dividing the frame, treated as a single binary number, by the binary number 1100000000000101, and

CCITT V.41 - the remainder after dividing the frame, treated as a single binary number, by the binary number 10001000000100001.

The latter two methods (known as Cyclic Redundancy Codes) can be shown [Tan81] to detect any odd number of incorrect bits, any two bits incorrect, any error contained within a 16 bit sequence and 99.998% of any other random bit errors.

Error Detection of out-of-order frames requires a sequence number field within the frame.

Each node has a variable that determines the next frame sequence number to expect from a

4. It is possible for the Physical layer to damage a frame in such a way that the checksums will still match. The checksum method should make that possibility very remote by detecting well the most likely errors on the particular type of physical link(s) used in the network.

connecting node. If a received (undamaged) frame does not contain the expected sequence number, the frame is considered *out-of-sequence*. If the sequence number is correct, an *acknowledgement* (ACK) is sent back to the transmitting node to indicate successful reception of an in-sequence frame. The transmitting node must retain all transmitted messages until informed by the receiver that transmission of the frame was successful.

The *Recovery* mechanism is a major part of a data link protocol. There are many types of recovery possible. The simplest mechanism sends a single frame and waits a (predetermined) length of time for the receiver to send back an ACK. Failure to receive the ACK will result in a "timeout" of the waiting transmitter and retransmission (and another wait) will occur. This continues until the frame is accepted. The receiver must continue to respond with an ACK even if the frame has been successfully received, to insure that its own ACK wasn't lost. This mechanism is called the stop-and-wait ARQ (Automatic Repeat Request) or PAR (Positive Acknowledgement with Retransmission) method.

This can be enhanced somewhat with a *negative acknowledgement* (NACK) sent by the receiver to inform the transmitting node that a "damaged" frame has arrived. This would result in immediate retransmission rather than waiting for timeout. Timing is still required to detect complete loss of the frame, ACK or NACK.

Further improvements are possible only if *pipelining* of the transmitter's frames is allowed; this allows a small number of frames to all be transmitted without waiting for an ACK. The number of sent but unacknowledged frames allowed is called the *send window*. If the receiver still insists that frames will only be accepted in order, the receiver is said to have a *receive window* of size 1. When the receiver sends a NACK, it will contain the sequence number that was last received correctly⁵. This allows the transmitter to determine from

which frame to begin retransmission. This retransmission strategy is called "Go-Back-N." Each frame in the send window must be timed separately. Timeout of a frame will result in the same actions as receipt of a NACK indicating the frame was lost (i.e., the frame and all following frames will be retransmitted).

If the receiver can also accept some frames out-of-sequence (and hold them until predecessors arrive), the receive window size determines the number of out-of-sequence frames that can be accepted. However, the receive window cannot be larger than $N/2$ where N is the number of unique sequence numbers. With such a receive window, an improved retransmission strategy called "Selective Repeat" may be used. The transmitter, on receipt of a NACK+sequence number, can retransmit only the next frame in the sequence. If that frame was the only missing one, the receiver will ACK with a sequence number that acknowledges the retransmitted frame and the frames that the receiver had previously accepted out of order. Timeout of a frame would result in retransmission of only that frame.

Another enhancement possible with pipelining is called *piggybacking*. This allows an ACKed sequence number to be placed in data frames that are being transmitted back to the original sending node, thus avoiding the transmission of a separate ACK frame. Since the ACKed sequence number typically is only a few bits in size, there is little frame overhead involved in this enhancement. However, to fully exploit piggybacking, the receiving node must delay transmitting ACKs for a time to allow transmission requests in the reverse direction to arrive. If there is no reverse traffic, then an ACK must be transmitted or the protocol will eventually "lockup" (i.e., stop sending new frames). Delaying for a period of

5. Some protocols indicate the sequence number *expected next*, instead of the *last received* number.

two or three ACKs has been shown [Lai82] to result in a significant amount of piggyback utilization, if the send window is of size 4 or more. If the number of "accumulated" ACKs is allowed to equal the window size, lockup will occur until some reverse traffic appears.

Link Control provides the mechanism needed to establish a connection over a link or to disconnect such a connection. The protocol attempts to keep both ends of a link either "connected" or "disconnected." In the disconnected state, no Network layer requests (except for *connection*) are accepted; most frames from the link receive a "I'm disconnected" response. Requests for *disconnect* while in the connected state may be honored immediately or may be deferred until there are no further unacknowledged frames at either end of the link. *Link Control* must also handle the case of a request for *connect* or *disconnect* when the state is already connected or disconnected, respectively.

Transparency is inherent in the byte-count protocols, but requires an "escape" mechanism in other character-oriented protocols. The escape mechanism operates by replacing "control" characters in the frame with a sequence of characters before transmission. The character sequences are replaced with the original characters when the frame is received. This is called "character-stuffing," in analogy to the "bit-stuffing" of bit-oriented protocols.

2.4 Examples of character-oriented protocols

Most of the earliest computer-communication protocols were character-oriented. The early teletype networks used 5 or 6 bit Baudot codes with embedded control characters to control the receiving devices. A list of major computer-to-computer protocols includes:

- | | |
|--------|---|
| BISYNC | (IBM's Binary Synchronous Communication protocol) is widely used, particularly in a multi-point configuration to handle groups of remote terminals. The node-to-node version operates over half-duplex lines. |
| X3.28 | (ANSI's protocol) standardizes on 10 ASCII control characters for link control and specifies several variations of a protocol for different |

configurations and applications.

IMP-to-IMP (ARPANET's sub-network protocol) has operated for 15 years providing service to well over 100 host computers. It operates 8 logical links over each physical link using a stop-and-wait protocol. NACK is not used, but the piggybacked acknowledgement field does contain the last-correctly-received frame number.

DDCMP (Digital Equipment's Digital Data Communications Message Protocol) uses the byte-count mechanism to achieve data transparency.

Other protocols that are less well-known usually use only minor modifications of the previous protocols. However, some notable exceptions to this have been implemented. The MININET [Ner84] local area network uses continuous transmission of short (32 bit) fixed-length frames to achieve a "lock-step" form of operation. By establishing a count of the number of frame periods required to send and receive initialization frames, each node can determine the number of frames always in transit between itself and another connecting node. No ACK or NACK control frames exist. Receipt of a damaged frame is indicated to the transmitter by having the receiver backing up its own frame sequence by the number of transit frames + 1, and retransmitting frames from that sequence number forward. The transmitter, on receipt of an out-of-sequence frame, backs up an amount determined by the out-of-sequence frame number and the frame number it expected to receive.

The French NADIR satellite link protocol [Ner84] uses explicit ACKs for every undamaged frame received, regardless of order. However, the ACK contains two sequence numbers and acknowledges receipt of all frames between those two numbers. Thus the transmitter can determine which frames, if any, have been lost or damaged and can thus retransmit them immediately. There is little need for a NACK with this method. In heavy traffic, the ACK for the following frame will indicate a missing frame. In light traffic, a timeout will eventually cause the frame to be retransmitted; in light traffic the time saved by a NACK

would have little impact.

2.5 Comer's Protocol – Overview

Comer, in an excellent book describing both a layered approach to and implementation of an operating system design [Com84], presented a simple, effective data link communication protocol. The protocol was presented in two sub-layers called Data Link level and Frame level⁶. Comer's *levels* together approximate the OSI Model's Link layer. The Data Link level is also similar to the Media Access Control sub-layer of IEEE Standard 802 [IEE84] with the Frame level acting as the IEEE802 Link Level sub-layer. However, Comer's Frame level protocol contains somewhat different capabilities than the IEEE802 Link Level sub-layer, since the latter has a virtual connection service available to higher-numbered layers. Comer's Frame level protocol does, however, offer reliable transport of individual data packets⁷ with no lost or out-of-order packets. (Detection of duplicates, if needed, must be performed at a higher layer.)

Comer's protocol is based on a particular processor inter-connection scheme called a unidirectional ring-shaped network. Each processor (or *machine*) in the network has an asynchronous, full-duplex bit-serial connection to two other processors⁸. The processors and connections together form a ring over which "frames" of character data are transmitted. One connection on each machine is considered the input port and is connected to the output port

6. The phrase "Data Link level" will be used to refer to Comer's "sub-layer" and it's extension in the next chapter. The phrase "Link layer" will be used to refer to that layer in the OSI Model.

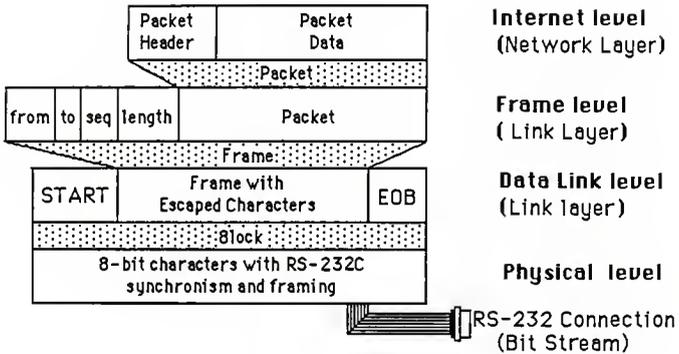

7. A "packet" is the unit of data exchanged at the Network layer. It is also, in this paper, used to describe the data the user wishes to send between two process existing on different physical machines. In effect, this lumps all data transmission requests to the Link layer from higher layers into the term "packet," regardless of the source of the data.

8. It is possible for one machine to be in more than one ring, thus allowing it to be used as a "gateway" for communication between the rings. That capability does not affect the protocol used over a single link, since the routing between networks is a function of the Network layer.

of a "neighboring" machine. The other connection is the output port and connects to the input port of a (usually) different machine. The flow of data messages between machines is always in one direction, and response characters (for ACK, etc.) are sent only in the reverse direction.

The general format of a frame in Comer's protocol is shown in Figure 1 along with the general interconnection of processes.

Protocol Units

Processes Implementing Comer's Protocol

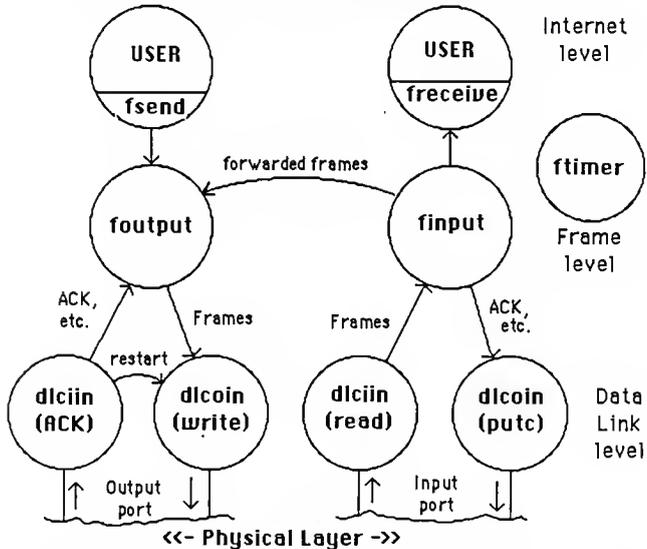

Figure 1. Comer's Protocol - Frame and Process Overview

Application processes request the transmission of packets to other machines on the ring. These packets are placed into frames and transmitted via the output port. Transmitted frames are received at the input port of the "next" machine on the ring, validated and examined to determine their source and destination. An ACK is sent back to the transmitting machine to indicate the frame was successfully received. Frames destined for the receiving processor are passed "up" a layer to a process that distributes the frames to various other application processes. Frames not destined for the receiving processor are usually forwarded via the output port to the next processor. However, if *no* processor "claims" a frame, it will eventually make its way around the ring and return to the originating processor; such frames with a source equal to the receiving processor do not continue to be forwarded. In this case, an error message is printed to the console. Please note that this overview does not describe Link layer error detection or recovery mechanisms.

2.6 Comer's Protocol – Data Link level

There are two processes at the Data Link level associated with each port. However, input port processing differs greatly from output port processing. The difference in processing is a result of requests from the Frame level, not in an internal knowledge of the type of port being served.

Each process is a classical *interrupt-driven device handler*. Comer, however, allows these to be viewed as a type of process that "waits" on interrupts when asked to do so by a Frame level request. The input interrupt handler (*dliin*) waits on incoming characters, receiving control when a character has arrived. (*Dlcoin*), the output interrupt handler, waits for outgoing characters to be transmitted, receiving control when it's time to send another character. While no appropriate Frame level request is active, any interrupt is ignored.

Data Link processing at the output port is initiated by the Frame level via a *write* request to *dlcoin*. Prior to the *write* request, a process must be registered with the ACK handler portion of the associated *dlciin* process to receive the ACKs, etc. sent to the output port by the receiving machine. The (*dlcoin-write*) process transmits a frame after "framing" its input data with the START character at the beginning and the EOB character at the end. In order to prevent these and other protocol-related "control" characters from appearing in the packet portion of the transmitted frame, "character-stuffing" is performed. "Control" characters in the packet are replaced by an ESC (escape) character followed by the "control" character modified by zeroing a particular bit. (All "control" characters have the particular bit set to one.)

The *dlciin-ACK* process will send any characters received on the output port to the previously registered ACK-receiving process, with one exception. If the received character is RESTART, *dlciin-ACK* checks the state of the associated *dlcoin-write* process by examining a shared variable. If the state is "INIT" (implying *dlcoin-write* is not currently transmitting a frame), the RESTART is sent to the registered process, as before. If, however, the state is anything other than "INIT," *dlciin-ACK* will force *dlcoin-write*'s state to "RESTART." The "RESTART" state informs *dlcoin-write* to stop transmitting the current frame and start retransmitting from the beginning. The RESTART character thus serves as a quick method of informing *dlcoin-write* that the frame currently being transmitted has already been rejected, and continued transmission is useless.

Data Link processing at the input port is also initiated at the Frame level, via a *read* request to *dlciin*. The *dlciin-read* process examines incoming characters, looking for the START character. It then stores the packet from the incoming frame, after "unstuffing" the two-

character ESC sequences by setting the previously zeroed bit in the character following ESC. The frame ends when the input buffer fills or EOB is received. During this processing, some character-related transmission faults can be detected. These are:

- a hardware-detected error (carrier loss, framing error, data overrun, etc.) and
- a character with the special "zeroed bit" already set following an ESC.

Any such fault causes *dlciin-read* to send a RESTART character back to the transmitting machine. The *dlciin-ACK* process would receive the RESTART and either initiate retransmission of the frame (as described previously) or notify the Frame level registered ACK process. The bit representation of RESTART has been chosen to not overlap ACK, NACK or SACK⁹ responses; the output process treats anything other than ACK or SACK as a NACK, so the net result of a RESTART is retransmission of the frame.

The Frame level sends ACK, NACK or SACK responses to the transmitting machine using the *putc* request. The *dlcoin-putc* process just transmits the requested single-character response.

2.7 Comer's Protocol – Frame level

There are three processes at the Frame level. The output Frame level process (*foutput*) accepts data for transmission from application processes, adds destination and sequencing information, sends the packet to the output port via (*dlcoin-write*), and retains a copy until successfully acknowledged by the next machine's input Frame level process (*finput*). Unacknowledged frames are also timed for retransmission. The *finput* process receives

9. SACK is a type of NACK that will also cause the expected sequence numbers at the sender and receiver to be reset. This will be described later.

frames from the input port via (*dlciin-read*), validates them and either sends the frame's data to the appropriate application process or forwards the frame to the next machine (via another *foutput* process). It also sends an ACK back to the transmitter via *dlcoin-putc*. A third process (*ftimer*) provides the *foutput* process with the timeout indication needed to force retransmission of an unacknowledged frame. The *ftimer* process sleeps unless such a frame exists.

To detect invalid frames, *finput* first verifies that the number of characters in the frame matches the length field within the frame. Missing or out-of-order frames are detected by assigning a sequence number to each frame when it is received from an application process. Comer's protocol uses a 3-bit sequence number in each frame to detect missing or out-of-order frames; each new frame is assigned an incremented sequence number (modulo 8). After sending a frame (via *dlcoin-write*), *foutput* waits for *finput* (in the receiving machine) to acknowledge the frame; this is commonly known as a stop-and-wait ARQ (Automatic Repeat Request) technique. Failure to receive an acknowledgement will be detected by the *ftimer* process and the unacknowledged frame will be retransmitted.

When *finput* receives a frame, the sequence number is compared to the expected sequence number. If they match, an ACK "character" with the "next expected" sequence number embedded is sent back to the transmitter. If the ACK is successfully received by the transmitting *foutput* process and the embedded sequence number matches the next expected sequence number, the unacknowledged frame is removed from *foutput*'s buffers and the *ftimer* process is put to sleep. If the received frame's sequence number doesn't match, a NACK "character" (with the current expected sequence number embedded) is sent to the transmitter. The transmitting *foutput* process will retransmit the unacknowledged frame

(without examining the NACK's expected sequence number) and wait for a response (ACK or NACK or SACK).

The transmitting and receiving ends of the link could get out of sync with regard to sequence numbers. If *finput*'s expected frame number is 4 and the message sitting in *foutput*'s buffer is 3 (or anything other than 4), then sending NACKs back to the *foutput* process will never (without some improbable bit mutilation) result in a message with a sequence number of 4 being retransmitted. To "solve" this problem, the *finput* process will send a SACK (in place of a NACK) if sequence number mismatches cause more than two NACKs on the same incoming message.

SACK informs the *foutput* process to reset its current sequence number back to 0; *finput* also resets its expected sequence number. Sequence number 0 will now be used to re-transmit the unacknowledged message and that number will be acceptable to the *finput* process. Note that the above scenario is not that improbable; if the ACK for frame 3 was lost, *foutput* will time-out and retransmit frame 3. However, *finput* will be willing to accept frame 4 only and will respond with a NACK. If this occurred, *finput* would eventually accept the data in frame 3 twice¹⁰, once as frame 3 (normally) and again as the new frame 0 (after NACKing three times).

Comer's protocol allows a single message to be transmitted to all machines on the ring network; this is known as a broadcast message. One particular value (zero) in the destination field of the frame header implies that the frame should both be passed up to the

10. Comer states that detection of duplicate messages must be at a layer above the Frame level. The detection mechanism must not rely on the Frame sequence numbers.

application's distribution process and forwarded to the next machine. When the frame has been forwarded completely around the ring, the originator of the broadcast message stops forwarding the frame.

Aside from the duplicate message problem and the lack of any rigorous bit mutilation detection, Comer's data link protocol appears to perform well. However, there are several extensions that would enhance it's efficiency and robustness, as well as adapt it for use in a non-ring network. All this is the subject of the following chapter.

3. PROTOCOL DESIGN

There are several problems with Comer's protocol (see below) which make it unsuitable for many applications. This chapter will describe possible extensions to the protocol and choose a subset of those extensions for further discussion. The resulting extended protocol will be described in detail, both in text and in modified state transition diagrams. Several scenarios will then be presented that show its operation under normal and failure conditions.

Two types of extensions to Comer's protocol are possible; those that add new capabilities (features) to improve efficiency, control, and flexibility (allowing alternate applications and architectures) and those that repair problems in the existing protocol. Note that while no formal verification of Comer's protocol was performed, examination of both the English description and the program code revealed several problems with the protocol. These include:

- no checksum over any portion of the frame,
- the possibility of passing duplicate packets to the Network layer,
- failure to detect excessively long frames and
- failure to detect a non-working link.

3.1 Possible Extensions

Any *checksum* mechanism could improve the ability of the protocol to withstand transmission errors. It is unusual to find any protocol that does not use at least a simple exclusive-or or sum-of-the-characters checksum.

Duplicate packets may be prevented by enhancing the NACK mechanism and removing the SACK acknowledgement. The detection of a *long frame* is a simple change; receiving a non-EOB character after the frame buffer is full would force the frame to be treated as

invalid. (Comer's implementation *assumed* an EOB would follow and passed the frame up to the Frame level.)

Another extension could be the addition of a *heartbeat* frame; it is periodically transmitted in the absence of other outgoing frames. The receiving process would complain if no incoming frames were detected over several *heartbeat* intervals. This would detect link failures (or lockup at the other end) even in the absence of outgoing traffic.

One capability that could add flexibility is *operation on non-ring architectures*. This would require that frames be passed to a "routing" process at the Network layer. This process would deliver frames after examining their destination and allow the output link for that destination to change over time.

A further extension could allow *full-duplex transmission of frames* over a link. Major changes to the single-character ACK/NACK/SACK mechanism would be required. Also, the Data Link input process must allow frames and acknowledgements to travel in both directions on a link.

Further flexibility could be provided by offering *virtual circuit* facilities at the Link layer, as proposed in [IEE84]. This would require (at least) the addition of another sublayer within the Link layer.

A related extension could be the provision of *datagram* facilities. This would allow a packet to be transmitted without retransmission or sequencing control. Errors in such packets would force them to be discarded without indication to either the originating or transmitting node.

A final extension for flexibility could add *unbalanced mode* operation to the protocol, in the spirit of HDLC. Several versions of Link Control (master, slave, etc.) would have to be

added, as well as a means for nodes to mutually agree on a version to use over a period of time. One could even imagine adding the ability to operate in a *multi-point* configuration (i.e., a master and several slave nodes connected to the same link), although this would require changes to the (assumed) RS-232C Physical layer.

A control extension could provide the ability to *stop (and start)* traffic over a link without loss of frames. This would allow a user-level process to request that the link be logically "disconnected" after ensuring that all preceding frames had been transmitted. All further requests for packet transfer from the user level would be blocked, but a request to reconnect the link would be allowed from either end of the link. Such a mechanism must ensure that neither end of a link is "disconnected" when the other end is "connected."

Another control extension could allow *direct control and monitoring* of the Link layer via user "Link control" messages. This would allow a user-level process to retrieve the status of the Link layer of a given link from any node, providing a method for collecting statistics on performance from a central location. It could also allow a remote node to "connect" or "disconnect" the link, as well as simulate packet input to the Link layer. If a "download protocol" capability also existed, it would be possible to load new protocols (of any layer) into the node from remote locations. Collectively, these capabilities would allow unattended operation of some nodes of the network.

Pipelining of frames and *piggybacking* of acknowledgements are obvious efficiency extensions. With pipelining comes the choice of various possible retransmission strategies such as "Go-Back-N" or "selective repeat." Pipelining would make the SACK resynchronization mechanism even worse since it could cause several duplicate frames to be passed to the Network layer. The effectiveness of Comer's RESTART mechanism could be

affected by the particular implementation chosen¹¹. Piggybacking, to be effective, would require that a few ACKs be postponed for a short period waiting for packets in the reverse direction.

3.2 Choice of Extensions

The following set of extensions has been chosen for use in the remainder of this paper.

Where necessary, the reason for choosing that extension is discussed.

- Checksums are added to all frames, via the CRC-16 technique.
- Duplicate frames are never passed to the Network or user levels. The SACK acknowledgement is dropped. Both ACK and NACK will carry the sequence number indicating the last frame received in sequence.
- Excessively long frames are detected and treated as "damaged" frames. It is unlikely that such frames would survive the checksum mechanism (approximately one chance in 2^{16}), but this extension is almost trivial.
- The *heartbeat* capability is added.
- Various network architectures are supported, although this is achieved primarily by inventing a routing process in the Network layer. The method by which the routing process performs its task is beyond the scope of this paper, however¹².
- Full-duplex transmission of packets and acknowledgements is added. The acknowledgement and control "characters" from Comer must be converted into control frames and distinguished from frames bearing packets.
- A "connect" and "disconnect" control facility is provided. The link is thus in either a "running" or "disconnected" state. User *fsend* requests and forwarded packets are denied in the "disconnected" state and the *heartbeat* mechanism is disabled. Incoming frames other than those associated with link control are discarded, with an AMDISC control frame being sent back to the transmitter.
- Pipelining is added to allow more efficient use of the physical link. The "Go-Back-N" retransmission strategy is chosen for both its effectiveness and

11. RESTART causes the current Data Link output transmission to abort. In Comer's protocol, this allowed retransmission of the current frame to begin immediately. With pipelining, the frame containing the error may not be the one being transmitted. If the retransmission strategy allows frames to arrive out of order, as in "selective repeat," then little would be gained in aborting transmission of a frame that was probably on its way to being accepted.

12. While this extension removes a capability from the original protocol (explicit forwarding of frames), note that Comer's routing at the Link layer was possible only because of the architecture. However, routing "off the network" via gateways was mentioned as a Network layer task in [Com84]. His total description of the routing process was that it "... computes a new route for the packet ...". I am thus following (at least here) in Comer's footsteps.

simplicity. Comer's RESTART mechanism will be only partially used. A means will be provided to abort any current frame transmission when frame retransmission is needed. Retransmission will be initiated at the Frame level. No use will be made of a RESTART character.

- Piggybacking of positive acknowledgements is added.

In choosing the particular extensions to make to Comer's protocol, the goal was to provide a non-trivial set of extensions without attempting to do everything mentioned above. The extensions listed above are certainly non-trivial. They entail changes to all areas of Comer's protocol, and also alter the interfaces to the adjacent layers.

3.3 Interfaces to Other Layers

Comer's Network layer could make only two requests of the Link layer for a given link, *fsend* and *freceive*. The extended protocol recognizes a third request, *fctrl*, to either establish the link connection or to disconnect the link. For a given link, a single process is still identified to receive all incoming messages (packets destined for this node). This process is responsible for distributing the messages to the proper applications.

The extensions require the addition of a routing process to the Network layer. Any accepted incoming frames are passed to this process. The Network layer sends outgoing packets to the Link layer for transmission; these have a priority indication so that, for example, forwarded packets may be transmitted before *fsend* packets that have not yet been transmitted.

No major changes in the interface to the Physical layer were required by the extensions. The full-duplex transmission capability of the layer is now being fully utilized. Both input and output continue to be viewed as a stream of characters. The single character ACK and NACK can no longer be used, since they could be confused with extraneous characters between frames; they also can benefit from the use of a checksum.

3.4 Protocol Overview

To simplify the presentation of the overall data link protocol, it has been divided into four sublayers [Boc79]. These correspond (almost) to the basic functions of character-oriented Link layer protocols listed in the previous chapter. These sublayers are (from lowest level to highest):

- Framing and Transparency - determining the actual characters sent over the physical link,
- Error Detection - validating the incoming frame,
- Data Transfer - controlling the sequencing of frames, the transmission of ACKs and NACKs, and maintaining frame ordering and
- Link Control - controlling the state of the link and handling requests for *connect* and *disconnect*.

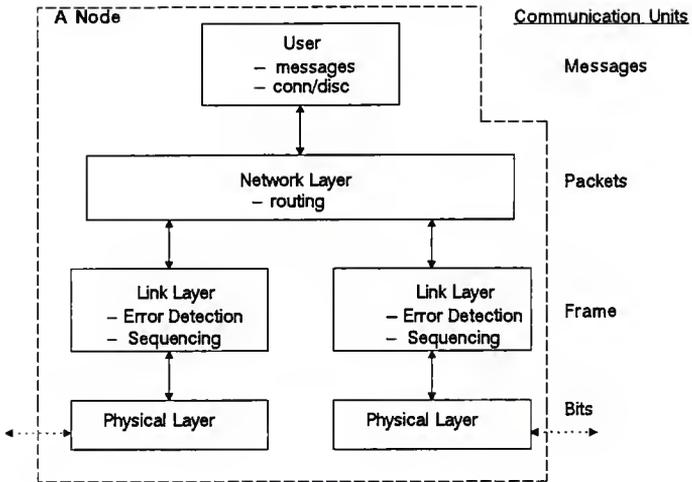

Each sublayer can be viewed as having its own protocol for communicating with peer sublayers in other entities. However, the boundary between sublayers is not as firm as between layers. For example, the sublayers can act together via shared variables to accomplish their task. This will be further explained in the descriptions of the protocol sublayers.

Each of the sublayer protocols will be described in text and some will be described by *modified transition diagrams* [Boc80]. These diagrams are an extension of the *state transition diagram* and allow transitions to manipulate variables via actions described in fragments of program code. Transitions are labeled and typically identified further as output transitions (underlined) or as non-output transitions (not underlined). A table links a transition label with the program code fragment. Associated with each transition (in the table) is an enabling predicate; the transition may be taken only if the predicate is true. If multiple transition predicates are true, the transition taken is randomly chosen; however, a rule for

arbitrating the decision can be specified. In addition, diagrams may be hierarchically dependent on other (higher level) diagrams. For example, the Data Transfer protocol is dependent on the state of the Link Control protocol, since Data Transfer only applies in the "connected" and "waiting_DISC" states.

To aid in understanding the protocol descriptions, an overview of the protocol layers and the sublayers within the Link layer appears on the next page. This is followed by a figure showing frame layout, "control" character assignments and types of frames.

Layer Overview

Four Sub-layer partitioning of Link Layer

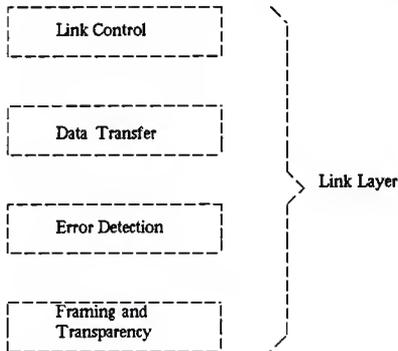

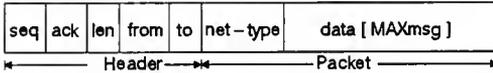

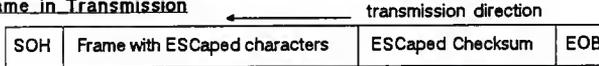

Figure 2. Design Protocol – Overview and Sublayers

Frame Layout

- seq = Information Frame (values '0' to '0' + MaxSeq)
or Control Frame (values '0' + MaxSeq + 1 to 255 decimal) [See Below]
- ack = Piggy-backed Acknowledgement (values '0' to '0' + MaxSeq)
- len = length of Frame (in character units) [3 or more for Control Frames]
[6 or more for Information Frames]
- from = ID of frame originator
- to = ID of intended destination (0 implies "broadcast frame")
- net_type = Network Level Information (type of data in Packet, etc.)
- data = 0 to MAXmsg characters of Packet data

Frame in Transmission

SOH = 0253, EOB = 0252, ESC = 0251 (octal)
Checksum = CCITT standard CRC calculation over non-ESCaped Frame

Frame Types

- | | | |
|-------------|--|--|
| | [Control Frame character IDs in ()] | |
| * INFO | Information Frame (contains Packet as above) | } Data Transfer
(only valid
if Link is up) |
| ACK (A) | Explicit Acknowledgement Frame
[sent only if no reverse INFO traffic] | |
| NACK (N) | Negative Acknowledgement
[sent on first bad frame in a sequence of bad frames] | |
| HEAR (H) | Heartbeat [sent occasionally if no other traffic] | |
| * START (S) | Start Connection ["ack" unused] | } Link Control
Frames |
| STACK (T) | Connection Acknowledgement
["from" contains next valid INFO "seq" value] | |
| * DISC (D) | Request Disconnect | |
| AMDISC (M) | Disconnect Complete ["ack" unused] | |

"*" indicates Frame Types that are timed and retransmitted if unacknowledged.

Figure 3. Frame types and layout

3.5 Framing and Transparency Sublayer

The Framing sublayer operates almost identically to Comer's Data Link level processes. The only major changes are the addition of a checksum just before the transmission of EOB and the elimination of the RESTART "control" character. The modified transition diagrams for both the input and output portions of the Framing and Transparency protocol appear in the next two figures.

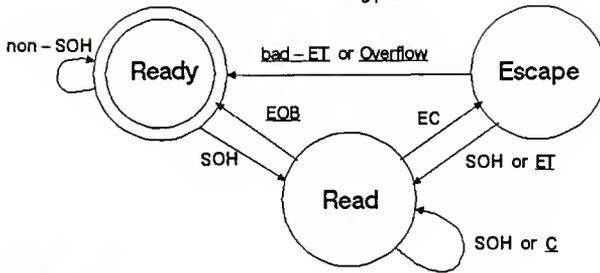

Note that a RESTART "control" character is not transmitted in the extended protocol. Errors that would have resulted in RESTART will now generate a NACK. However, a related mechanism is implemented using a global variable *G_restart*. The Data Transfer sublayer sets *G_restart* only when beginning to retransmit a series of frames. The Framing sublayer will stop transmission of the current frame (if any) if *G_restart* is set. Framing will also reset *G_restart*. This allows any transmission to be stopped immediately, rather than waiting for it to complete, so that the retransmission can begin sooner.

As an example of this protocol:

<----- transmission direction

Header,A,B,ESC,F,SOH	:original Frame characters
SOH,Header,A,B,ESC,[ESC],F,ESC,[SOH],cksum,EOB	:as transmitted
Header,A,B,ESC,F,SOH,cksum	:passed to Error Detection

where [bracketed] characters represent the original characters with bit 7 set to zero.

Global

G_restart – set by foutput()

Initial State

Ready

Variables and Functions

count : int

buf[MAXfr] : char array

ch : char

send(X)

readCH()

unescape(ch)

number of characters stored in "buf"
 buffer to hold result frame
 holds last character read
 send frame or error status

to Error Detection sub-layer
 reads next character from Physical Layer
 returns character to substituted for "ch" when
 following ESC on input (returns - 1 on error)

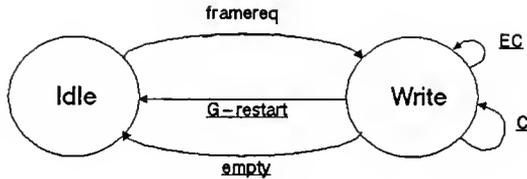

Note: Prior to testing for the Transition, an implied "ch = readCH()" is executed.

If multiple Enabling Predicates are true, the first listed Transition is used.

The notation "[oldState > newState]" indicates State Transition from diagram above.

<u>Transition</u>	<u>Enabling_Pred.</u>	<u>Action</u>	<u>Meaning</u>
SOH	ch == SOH	count = 0	Start processing chars.
["any" > Read]	ch != SOH	-	Wait for it!
[Ready]	EQB	send(buf)	Send frame up
[Read > Ready]	EC	-	Saw ESC
[Read > Escape]	C	buf[count + +] = ch	Store ch
[Read]	{SOH,EQB,ESC} &&count <= bufsize	send("error2")	Indicate frame TOO LARGE
<u>Overflow</u>	count > bufsize	send("error1")	Indicate BAD char. was found
["any" > Ready]	ET	buf[count + +] = unescape(ch)	Store un-escaped character
[Escape > Read]	bad-ET	send("error1")	Indicate BAD char. was found
[Escape > Ready]			

Figure 4. Framing and Transparency (Input)

Global

G_restart - set by output

Initial_State

Idle, fr = framereq(), G_restart = false

Variables and Functions

fr: frame pointer
frcount: integer

cksum[2]: char
ch: char
next()
escape(x)
escapec(c)
framereq()
crc(fr,count)

address of frame to transmit
number of frame characters
remaining to transmit
holds checksum in character form
holds character from the frame
returns next character from frame
true if x should be escaped
replacement character for c when escaped
returns address of frame to send
returns CCITT CRC checksum

<u>Transitions</u>	<u>Enabling Pred.</u>	<u>Action</u>	<u>Meaning</u>
framereq [Idle > Write]	framereq() completes, returning char.	frcount = fr.length cksum = crc(fr,frcount) write SOH ch = next()	Start sending frame
C [Write]	frcount > 0 && !G_restart && !escape(ch)	write ch ch = next() frcount - -	Transmit character
EC [Write]	frcount > 0 && !G_restart && escape(ch)	write ESC ch = escapec(ch) write ch ch = next() frcount - -	Transmit character requiring ESC processing
G_restart [Write > Idle]	G_restart true	release fr	Stop early
empty [Write > Idle]	frcount <= 0	if(escape(ch=cksum[1])) write ESC ch = escapec(ch) write ch [.. repeat for cksum[2]] write EOB release EOB	Finish sending frame

Figure 5. Framing and Transparency (Output)

3.6 Error Detection Sublayer

The error detection sublayer is responsible for handling errors reported by the Framing and Transparency (input) sublayer and for detecting any other errors in the frame. This protocol does nothing to output, since the Frame and Transparency sublayer computes and sends the checksum. In effect, Error Detection provides a function called *send* that is called by the Framing and Transparency sublayer. A function called *sendon* is then used by Error Detection to pass frame and error indications up to the Data Transfer sublayer. The pseudo-code for the *send* function is shown in the figure below.

```
send(fr,count,status)      fr=frame address
                           count=no. non-ESC characters read
                           between SOH and EOB.
                           status=0 unless error
                           detected by Framing sublayer.
{
  if (status != 0) {
    sendon(status);      pass error to Data Transfer
    return;
  }
  count = count - 2;      remove checksum from frame
  if ( count < MINfr ) {
    sendon(4);           frame too short
    return;
  }
  if ( count != fr.len ) {
    sendon(5);           count incorrect
    return;
  }
  if ( crc(fr,fr.len) != checksum at end of frame) {
    sendon(6);           bad checksum
    return;
  }
  sendon(fr);           send good frame to Data Transfer
}
```

Figure 6. Error Detection Diagram

3.7 Data Transfer Sublayer

This sublayer implements the sequencing checks that ensure correct (in-order) delivery of packets to the Network layer. It implements a seven frame sending window and a single frame receive window. The "Go-Back-N" retransmission strategy is used. Operation of the Data Transfer sublayer occurs only when the LinkState (in Link Control) is "connected" or "waiting_DISC."

Four variables control the action of the protocol:

- ExpectedF - this is the sequence number of the next frame that can be acknowledged and sent up to a higher level,
- ExpectedA - this is the sequence number of the oldest unacknowledged frame (if any) waiting for acknowledgement,
- NextF - the sequence number to be associated with the next frame sent over the link and
- NoNack - a boolean that allows a NACK response if true.

In general, ExpectedF is incremented when a frame is sent up to a higher level. ExpectedA is incremented for each unacknowledged frame that is acknowledged by an incoming ACK. NextF is incremented each time a frame is added to the unacknowledged send window (up to 7 outstanding). NextF is set to ExpectedA to begin a "Go-Back-N" retransmission, and the *G_restart* global variable is set. NoNack is initially *true*, becomes *false* if a NACK is sent and then becomes *true* when the ExpectedF frame is finally accepted. (Only one NACK is sent on an error for a particular value of ExpectedF, to avoid swamping the link with long series of NACKs if long series of out-of-sequence frames are being received.)

This strategy of avoiding redundant NACKs has an unfortunate failure mode¹³. While

unlikely, the failure "stalls" the protocol until some reverse traffic (to the transmitter) tells the transmitter the last frame received in sequence (via the piggyback ACK). To "fix" the failure without reverse traffic, the HEARtbeat frame (essentially internal traffic) is transmitted if no reverse traffic appears in a defined interval.

In order to effectively use the piggyback ACK, the explicit ACK frame is delayed for up to three incoming frames (or a short traffic-less interval). Any outgoing traffic during the delay will cancel the explicit ACK.

13. The scenario leading to this state is described in the Data Transfer Failure Scenarios figure later in this chapter. The problem occurs only when there is no traffic in either direction other than the frame being retransmitted. Two failures are also required to force this condition, the loss of the ACK sent when the frame was originally correctly received and the loss of the NACK returned the first time the frame was re-received.

No State Diagram -- just reacts to incoming frames
and requests to send new Packets.

Globals

```
LinkState:{DISC,waiting_DISC,CONN,waiting_CONN}
           from Link Control
ExpectedF:Seq next incoming frame expected
ExpectedA:Seq next acknowledgement expected
NextF:Seq     next seq. number for outgoing frame
buffered     total frames buffered in Data Transfer
             (Variables of type Seq use modulo N arithmetic)
             ( N = a small integer, typically a power of 2)
```

Variables and Functions

```
windowed     frames currently in window (max. Nwindowed)
DoNack:bool  true initially and when good ACK arrives.
             false if ExpectedF already NACKed once
FR           type of Frame Received {INFO,ACK,NACK,HEAR}
send(type,num) adds "type" frame to Transmit Queue with
              ack = (ExpectedF-1). If INFO, num =
              frame number in window. Starts frame timer
              and ACK timer. Sets "lastACK" to (ExpectedF-1).
between(x,y,z) true if x<=y<z, modulo seq. numbers.
sendup()      sends packet in current frame to Network Layer.
```

The following only operate when LinkState={CONN,waiting_DISC}

```
Frame or event  Action when frame received
-----
```

```
INFO,seq,ack: if (seq == ExpectedF) {
               sendup(); /* Frame to higher layer */
               ExpectedF ++;
               DoNack = true;
             }
             else if (seq != ExpectedF && DoNack) {
               send(NACK,0); /* Send NACK if 1st time */
               DoNack = false;
             }
             /* The following segment is referred to as HANDLE ACK below */
             while between(ExpectedA,ack,NextF) {
               remove frame from window
               buffered --;
               windowed --;
               ExpectedA ++;
               stop timer for frame, start ACK timer
               add new frame to window from Request Queue,
               if Request Queue not empty,
               move from Request Queue to window
               send(INFO,NextF)
               NextF++;
             }
             /* End segment called HANDLE ACK */
ACK:          [ HANDLE ACK as above ]
```

Figure 7. Data Transfer Diagram (Part I)

```
NACK:      while between(ExpectedA,ack,NextF) {
            remove frame from window
            buffered --;
            windowed --;
            ExpectedA ++;
            stop timer for frame
            if Request Queue not empty,
                move from Request Queue to window
                NextF++; /* DON'T send() yet! */
        }
            /* Start retransmission here */

                add frame to window and send(INFO,Nextf)
                NextF++;
                windowed ++;
            }
            else {
                add frame to Request Queue
            }
            buffered++;

error:     /* Bad Frame received */
            if (DoNack) send(NACK,0);
            DoNack = false;

HEARfail:  /* Failure to receive HEARTbeat */
            Print failure message
```

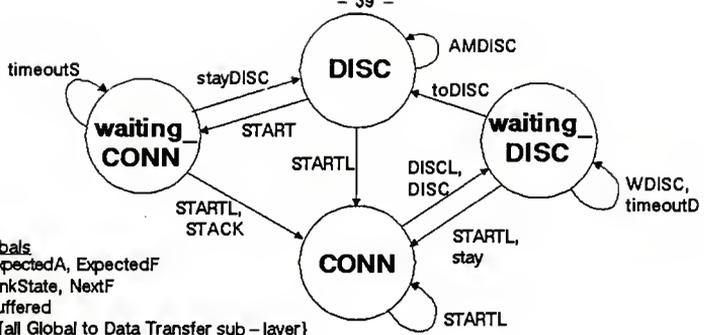

Figure 8. Data Transfer Diagram (Part II)

3.8 Link Control Sublayer

Link Control allows the user or other end of the link to request that the link be placed into the "connected" or "disconnected" state. On connect requests, the connection is attempted MAXattempts times before giving up and reporting the problem. The connection will synchronize properly the sequence numbers expected at each end of the link. A connect request from the link to an already connected link is assumed to be from a node that "crashed." The protocol will resequence the sequence numbers such that any unacknowledged frames in the "connected" node will be accepted by the requesting node. The requesting node is required to begin its sequencing at 0, but then a "crashed" node probably lost any unacknowledged frames anyway. User requests to send or receive packets over a "disconnected" link will be refused.

Disconnect requests can originate either from the user or over the link. The timeout interval is fairly long, because the AMDISC acknowledgement is not sent until all unacknowledged frames have been acknowledged. Disconnect requests have a sequencing problem also. It is possible for an unacknowledged frame to be retransmitted many times without an ACK or NACK being returned¹⁴. If disconnect had to wait until this "lost" frame was acknowledged, a user would be waiting a long time for the request to complete on what should be an idle link! To prevent the long waiting time, an *ack* field appears in the DISC frame to explicitly acknowledge such frames. (The HEARtbeat frame would eventually cure this problem, since it also explicitly acknowledges the last frame received in sequence.)

¹⁴. This is described in the Data Transfer section as a justification for the HEARtbeat frame.

Globals
 ExpectedA, ExpectedF
 LinkState, NextF
 buffered
 {all Global to Data Transfer sub-layer}

Initial State
 DISC
 NextF, ExpectedF, ExpectedA, buffered = 0

Variables
 attempts : integer counts START or DISC frames sent
 FR : frametype type of Frame received
 receivedDISC : {true,false,waiting}

Note: Enabling Predicates are tested in the order listed. Testing occurs only after an event has occurred. Events are "new Frame received" (causing FR to be set), "user transactions", and "timeouts" of various types. Portions of Predicates referring to the FR variable apply only if the event causing evaluation was "new Frame received."

Transition	Enabling Pred.	Action	Meaning
START [DISC > waiting_CONN]	user transaction fcontrol(CONN)	LinkState = waiting_CONN attempts = 0 start STARTtimer ExpectedA, NextF = 0 ExpectedF = 0 send START	CONN from user, attempt CONN.
STARTL ["ary" > CONN]	FR = = START	LinkState = CONN ExpectedF = 0 stop STARTtime & DISCtimer send STACK(ExpectedA)	CONN from Link, force CONN, Data Transfer will retransmit window (if not empty)
STACK [waiting_CONN > CONN]	FR = = STACK(n)	LinkState = CONN ExpectedF = n Stop START timer	CONNECTed! "n" is the frame seq. # other end will start using.
AMDISC [DISC]	FR != START & FR != AMDISC	send AMDISC	Tell other end we're DISConnected
haveDISC [waiting_DISC]	(FR = = AMDISC or FR = = DISC) & buffered = = 0	receivedDISC = true	Finally got it! (toDISC may be true now!)

Figure 10. Link Control Diagram (Part II)

3.9 Operation Scenarios

The remainder of this chapter demonstrates the performance of the various sublayers just described. No attempt has been made to show all possible sequences within each sublayer. However, all non-trivial transitions within each of the Link Control and Data Transfer sublayers are used by at least one scenario. The scenarios use a time sequence diagram to show the transmission and reception of frames and their relationship to the peer sublayer at the other end of the link.

The diagram is read from the top down. The left side of page represents one end of the link, the right represents the other. Across the page, the first column represents the state of the Data Transfer or Link Control variables of interest in that scenario. Next is a field describing the frame being sent or received. The center (usually white) column represents the physical link, with comments occasionally indicating something other than normal transmission. The remaining two columns represent the frame being sent or received and the state variables of interest, respectively, for the other end of the link. Events occurring at the same time or in random order are represented by having them appear on the same line of the diagram.

A shorthand method of describing each frame is used. The frame type is identified by its acronym (see "Frame types and layout" above), followed by the sequence number and acknowledgement number, where applicable. Since the sequence number applies only to INFO frames, any number following other frame types is the acknowledgement number.

A "+" before the frame type indicates reception of that frame, a "-" indicates the frame is being transmitted. The value (before reception or transmission) of the Data Transfer

variables [ExpectedF, ExpectedA and NextF] are represented in some instances as "[x,y,z]" on the appropriate side of the page, with "-" indicating a "don't care" value of the associated variable. The center of the page represents the physical link, normally blank. An X indicates the associated frame was damaged in transit while an L indicates the frame was lost.

Another shorthand notation indicates that the user's message was removed from the "unacknowledged frame" buffer. This is represented as "-msgN," typically next to the reception of an ACK, where N represents the frame sequence number. The notation "-hostN" will be used to indicate that a received frame with sequence number N has been passed up to the Network routing process (in order and without duplication).

Light traffic – single INFO, ACK, then single INFO, return INFO with piggyback ACK, ACK

Bracketed Variables are [ExpectedF(EF), ExpectedA(EA), and NextF(NF)]. They are only shown when a change in value occurs and reflect the values after the Frame or < event > is processed (i.e., "Action" portion of applicable transition diagram(s) has/have finished.). < Events other than Frame transmission/reception are shown like this. > and {Comments are shown this way.}

4. IMPLEMENTATION

Implementation of the protocol from the previous chapter is in the Concurrent C [Geh84] language running on a VAX 11/780 under the 4.2 Berkeley Software Distribution version of UNIX™. The choice of the implementation language was made with the knowledge that Concurrent C was not (yet) well-known and that transportation of the protocol to other systems would not be trivial. However, Concurrent C does provide an easily understood method of process interaction. Many of the transitions appearing in the modified state transition diagrams can be mapped into Concurrent C in an obvious manner. Thus the leap from diagram to code is not so difficult, and there is less chance of incorrectly translating a protocol description into code.

4.1 Concurrent C Facilities

A short summary of the facilities provided in Concurrent C will aid in understanding the implementation (and the comments in this chapter). Concurrent C allows processes to interact through a concept called the extended rendezvous; two processes request the rendezvous, synchronize and exchange information and then continue their concurrent operation. The two processes are not equals during a rendezvous. One process requests the rendezvous while the other accepts the request; the request and accept can be executed asynchronously and each will wait on the other. However, the accepting process is allowed to accept requests from multiple processes and may even have multiple types of accepts all open at the same time. The requesting process is allowed only one pending request to one

UNIX is a trademark of AT&T Bell Laboratories.

process at any one time. It is possible to revoke the request, but typically the requester is blocked until the request is accepted¹⁵.

In addition to the Concurrent C language, a facility called the Concurrent C Window Manager [Smi84] is provided. On UNIX, the Window Manager allows controlled interaction with various processes within a Concurrent C program from a single display terminal. Input can be directed to individual processes, even though several may be requesting input simultaneously. Output is directed to virtual windows, and the Window Manager controls which virtual windows appear on the terminal at any given time.

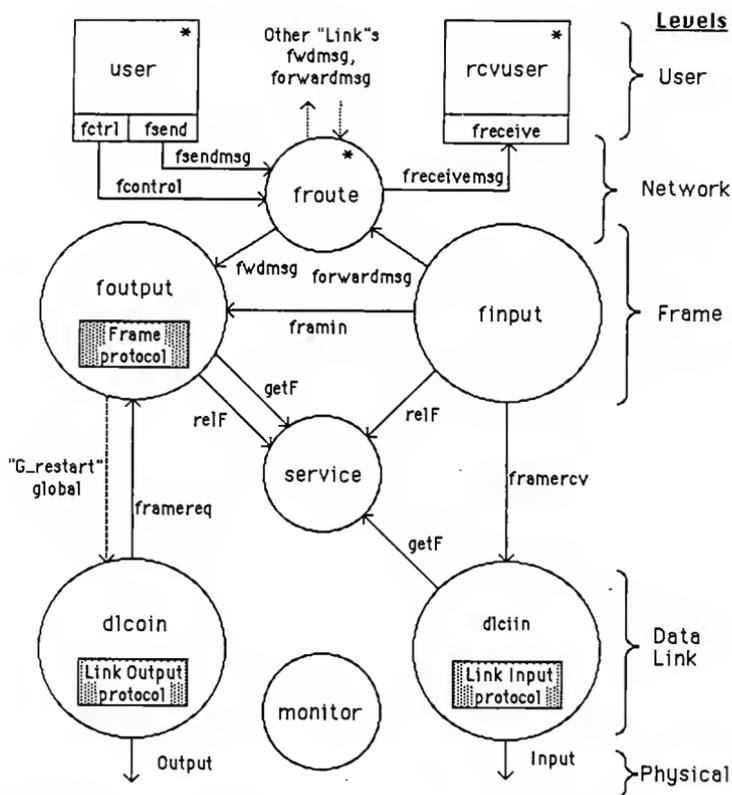

4.2 Implementation Structure

The approach of mapping each protocol sub-layer into Concurrent C processes was not used in this implementation. Such a mapping would require the use of monitors or buffer processes between many of the protocol processes to prevent blockage. Efficiency would suffer from the operation of several small protocols on each frame. Therefore, the sublayers were combined back into the two levels that Comer used, a Frame level and a Data Link level. The processes bear the same names as Comer's Link layer processes, but communicate via Concurrent C transactions rather than global data structures, semaphores and interprocess messages.

The processes also perform somewhat different tasks at the Frame level than the corresponding processes in Comer's implementation. Rather than using separate input and output processes cooperating to implement the Frame level protocol (as in Comer), the

15. There may be an analogy in male/female protocols (social etiquette in *accepting invitations*), but I will leave that investigation to others. (See [Foc55] or, for a more formal treatment, [McC77].)

Frame level protocol is placed entirely within one process, *foutput*. An *input* process is still used, but only to retrieve incoming frames from the Data Link layer, notify *foutput* and send acknowledged frames up to the Network layer. The result of this shuffling is called the Implementation Model. A diagram of the processes and protocol placement follows.

Frame protocol combined Link Control and Data Transfer protocol.

Link Output protocol Framing and Transparency (output) protocol.

Link Input protocol combined Framing and Transparency (input) and Error Detection protocol.

Labeled arcs are Concurrent C transactions, the accepting process is at the arrowhead end of the arc.

Figure 26. Implementation Model

4.3 Implementation Model

The Implementation Model (just "Model" from now on) provides a fixed set of services between a limited number of processes and assumes that the protocol will fit into the indicated places without resorting to the use of global variables or communication paths other than those shown. Thus, while the Model can certainly support the extended protocol described in the previous chapter, it can also support alternative protocols. Appendix 1 shows the pseudo-code for the Concurrent C processes implementing the Model. Where [... protocol] is shown, the appropriate portion of the protocol is executed.

In general, the Model operates by accepting packets from user processes and the *froute* process, and delivers them to the *dlcoin* process for transmission. The *finput* process waits on *dlciin* to read a packet (or indicate reception of a damaged packet), then passes the frame to *fouput* for analysis. The status returned by *fouput* determines whether the frame is passed up to the *froute* process. The heart of the retransmission and sequencing of frames is controlled by *fouput*. The *service* process is a concession to efficiency. It provides a frame management service that allows frame addresses to be passed between the processes at the Frame and Data Link levels, instead of copying the data.

4.4 Implementation

The protocols from the previous chapter are implemented within the Model using, where appropriate, code that reflects the state transition diagrams. It is thus not difficult to determine that the protocol code matches the diagrams closely. Many of the predicates placed on transitions in the diagrams are handled by *guards* and other facilities provided in Concurrent C.

Appendix 2 contains the code for the implementation, as well as supporting files.

4.5 Test Facilities

To allow control and monitoring of various processes in the Model, a process called *Monitor* was implemented. This process reads test control input from a Virtual Window and acts upon that input. Associated with each link's processes and with the local network layer's processes is a block of *Monitor* variables accessible only by those processes and by the *Monitor* process. The input to *Monitor* is one of the following (where *var* is the name of a *Monitor* variable):

- ~Mx - enter *Monitor* variable access mode for the nodeID or linkID specified by "x" (required before the following inputs apply),
- d var - display the value of the *Monitor* variable *var*,
- d - display the value of all *Monitor* variables,
- s var - set *var* to 1,
- r var - reset *var* to 0 and
- Q - exit *Monitor* access mode.

Dump, set and reset are rather primitive, but provide the means to control and monitor the other processes. This is accomplished by placing some "instrumentation" code within each of the processes. The instrumentation code allows limited access to the *Monitor* variables¹⁶.

Each variable is used in one of three ways; as a counter, picture or flag.

A counter variable is incremented each time the

```
COUNT(var);
```

¹⁶ Concurrent C does not allow access directly to global variables from a process, nor is a process such as *Monitor* allowed access to the local variables of other processes. The only mechanism (besides transactions) for communicating between processes is global variables, but they must be accessed by functions defined outside the processes.

statement appears in the Concurrent C code. The counter variables (and the others) are initially 0.

A picture variable provides a means to tell *Monitor* an (integer) value last computed at some point within a process. For example,

```
PICTURE(var,value);
```

takes a snapshot by placing "value" into the *Monitor* variable "var."

A flag variable controls the execution of alternative code, based on the variable being "set" or "reset." For example, to simulate the effect of a lost ACK when "var" is "set,"

```
if ( ! FLAG(var) ) {
    send ACK;
}
```

or to block a process from further execution,

```
while( FLAG(var) ) delay 1;
```

The *Monitor* variables are defined at the beginning of each compiled unit in a complex structure and must be initialized there. This requirement is most conveniently met through the use of macros defined in the C header file "monvars.h".

Since *Monitor* can dump and change variables as the processes execute, it can, with intelligent placement of "instrumentation," be used to trace a process's execution and to control dynamically the failure testing of a protocol.

4.6 Protocol Testing

The protocol's processes (collectively called *Proto*) can be tested by executing *Proto* twice (from two separate display terminals). In this instance, two arguments must be provided to *Proto*, one is the nodeID of this instance of *Proto* and the other combines the linkID used by

Proto to identify the (single) link and the name of the I/O port acting as this end of the physical link. The ports must be physically connected together, of course. An example of input to begin a typical test session is:

```
Proto A 2,/dev/tty3 [Node A reaches Node 2 using device tty3]
```

```
Proto 2 A,/dev/tty4 [Node 2 reaches Node A using device tty4]
```

implying that the *tty3* and *tty4* ports are physically connected together. Many other test configurations are possible; refer to the manual pages for "*Proto*."

After initialization, the Window Manager will display the execution status of some of the processes on the terminal screen. The contents of the first four virtual windows will also be displayed. Packet transmission is initiated through input to the virtual window associated with a *user* process (or the *Monitor* window). Access to *Monitor* variables is through input to its virtual window as previously described.

4.7 Implementation Limitations

The implementation "works around" several deficiencies in the parts from which it is constructed. UNIX, in general, does not allow controlled inter-process communication between arbitrary user processes. This was one of the reasons for choosing Concurrent C as an implementation language. On the other hand, Concurrent C cannot currently maintain the effect of concurrent processing when requests to the operating system block execution of the underlying UNIX user process. This limitation (concurrency during operating system requests) requires, for example, the use of non-blocking *read* requests from the input device. (This forces a "polling" approach to read requests, something that non-concurrent languages

must typically do.) Protocols that require a multiplicity of readers or other blocking requests to UNIX will have difficulty fitting into the Model *and* achieving concurrent operation. One can hope that improvements in the implementation of Concurrent C would allow "true" concurrency at the UNIX process level, perhaps even maintaining the flexibility that the Window Manager provides.

Also, the extended rendezvous process interface of Concurrent C (and ADA) has difficulty handling the asynchronous event and message passing that is available in a "process control" or message-based environment. By suitable use of several "server" and "buffer" processes, these difficulties may be circumvented, but the Implementation Model cannot claim to handle such needs.

The Model itself, given the above limitations, makes further assumptions about the way that various processes communicate. For example, the user-level process receiving incoming messages is assumed never to communicate anything back down to the Link layer. To allow *freceive* to make flow control requests or to reject frames (they have already been acknowledged) would require some major surgery on the Model.

5. CONCLUSION

This report has presented an extended protocol for the Link layer of a computer communications network. While based on an already-published protocol for ring networks, the extensions have removed the requirement for a ring architecture, improved error detection, increased utilization of the link, and added a degree of control over the link. The result is a protocol that provides a solid base for further extensions or for supporting development of higher protocol layers.

The use of the *monitor* in the implementation, together with the facilities provided by the Window Manager, allows the execution of the protocol to be observed and controlled from a single terminal representing the processes operating at one end of a link. This provides a more satisfying and useful test facility than batch test scripts and reams of printed output tracing protocol execution.

As the applications for computers increase and their need for information grows, it is likely that the need for usable, efficient protocols and implementations will increase. While the protocol and implementation described in this paper are useful and reliable, it cannot be claimed that the ultimate Link protocol has been achieved. The work does, however, provide a foundation for development by others.

5.1 Future Efforts

There are several areas related to this report that are worthy of investigation. First, formal verification of the protocol would provide some solid evidence of the soundness of the protocol. Second, Chapter 2 itemized several possible extensions that were not designed into the protocol. Some of these, in particular the Virtual Circuit capability and the remote

control of nodes, would be major undertakings. Designing and implementing the Network layer routing process would also be an interesting exercise.

In the implementation area, it would be informative to see this Concurrent C implementation compared to an implementation in other languages supporting concurrency. Of course, an implementation in a non-concurrent environment using the protocol descriptions in Chapter 3 would also be possible. One interesting non-concurrent environment would be a micro-computer or work-station, with all communication with other computers using the protocol. Mapping the design into a tty protocol within the UNIX operating system kernel would produce an efficient version of the protocol. An alternative would be placement of the *dlciin* and *dlcoin* processes into the kernel (or a programmable I/O device), with the Frame level remaining as user processes.

It has been said that every communication protocol evolves toward more complexity until it ceases to be used. As a project for those believing in the phrase "small is beautiful," some of the extensions could be removed or revised and the resulting protocol compared to the original.

ACKNOWLEDGEMENT

I would like to thank several individuals for their support in the preparation of this report. The advice and assistance of Dr. Richard McBride made the preparation of this report an educational and even enjoyable experience. My supervisor granted me this time undisturbed by any work-related emergencies. And my wife, Linda, and my family have provided the encouragement and sacrifice needed to allow this effort to take place.

APPENDIX 2

Implementation Code of the Extended Protocol in Concurrent C

```

/***** Proto *****/
/* (CURRENT VERSIDN = A.1, see Version History below)

```

Proto,
 A Robust DSI Layer 2 Link Protocol
 by Alan L. Varney
 Summer 1986 & Summer 1987

Proto was designed and implemented as part of the requirements for a

Master's of Science degree at
 Kansas State University, Manhattan, Kansas

Proto is based primarily on the design (but not the implementation) of a character-oriented Layer 2 Link protocol by Douglas Comer and documented in his book,

"Operating System Design: The XINU Approach,"
 Prentice-Hall, Englewood Cliffs, NJ, 1985

Comer's design was modified and enhanced to support architectures other than a ring network and a single-frame transmit window. The details, as well as a review of Link transmission and protocols, are in the

"The Design and Enhancement of
 an Existing Data Link Protocol."
 by
 Alan L. Varney

Masters Report, Kansas State University, Summer 1987

Note that a printed listing of Version A.0 forms Appendix II of the Report.

Proto is written in a language called Concurrent C. It supports the basic concept of an 'extended rendezvous' model for concurrent process interaction and control. Due to differences in operation and support facilities available in various UNIX implementations, Proto can be "tailored" to some degree. The code follows (mostly) a standard for portable C coding used in various books by Plum Hall, Cardiff, NJ. In particular, the book

"Reliable Data Structures in C", Plum, Thomas [1985]

specified the format of data-type identifiers and some of the commenting style used within Proto. Like many standards, the Plum Hall standards for coding are not perfect, but at least they are PUBLISHED standards. Where convenient, the data-types are credited to "Plum Hall." These data-type definitions may be changed to tailor Proto to different machines and environments.

----- Version History -----

(version name.number, author, date and reasons for change)

Version A.0, Alan L. Varney, 12/5/86
 The original, untouched Proto...

Version A.1, Alan L. Varney, 12/13/86
 "proto.cc" source split into "README",
 "linklayer.cc" and "natlayer.cc",
 also a mekefile introduced.

/* COMPILATION OPTIONS for Proto

As mentioned, the Proto interface can be changed to adapt to various Physical Layer restrictions by changing the values associated with the "Protocol magic characters" in the "proto.h" file and by adding/changing information in the FT_init function code. (Lines consisting of the "ESC_entry" macro call.)

Monitor variables are provided (in MONITOR-containing implementations) that allow control over TRACE data collection, and provide event counts and snap-shots ("pictures") of various internal process variables. The Node has a table (named MON_TBL) of its MONITOR variables. Each Link has a table of MONITOR variables defined by the Mvars pointer in the Link_table structure. These variables can be examined/changed by MONITOR. Three macros (defined in monvars.h) control the use of the variables by other processes. The FLAG macro returns the value of a Flag-type MONITOR variable. The COUNT macro increments a Count-type variable, and the PICTURE macro sets the named variable to a specified value. Additionally, the TRACE macro is a shorthand way of testing a FLAG variable and, if non-zero, printing some useful output. TRACE is a no-op if 'BTRACE' is undefined during compilation.

Finally, the functionality of Proto can be tailored by "turning off" 2 major parts of Proto. The "Window Manager" interface can be turned off (saving some space and much screen I/O overhead), with the loss of many of the "status" messages and process observation capabilities normally available.

For primitive (but run-time efficient) testing, a MONITOR process is normally provided that allows for the activation and monitoring of processes via compiled-in run-time checks. If desired, the MONITOR interface can also be "turned off" at compile time.

With both the "Window Manager" and MONITOR removed, Proto has 1 computer terminal (or "user") interface. Usas of this configuration are as a remote process at the "other end" of the Data Link or on machines where the normal configuration strains the system.

Compiling with the -ONDWM option leaves out any code related to the "Window Manager", and alters error messages normally placed in one of the display windows. If the NDWM option is selected, any "routine" status output is directed to 'stderr' (This should be re-directed by the user to a 'log' file.) The MONITOR is the source for any terminal input with this option, and typically generates the only terminal output, other than that printed by 'rcvuser' on receipt of a valid Packet. Input to user processes is not possible with this option; however, the MONITOR can perform any action that a "user" process could perform. Major problems in other processes may result in output at both the 'standard' and 'stderr' outputs.

Compiling with the -ONDMMONIT option removes any messages (and code) associated with the MONITOR process. If -ONDWM is also selected, there will be only 1 "user" to interact with Proto directly, receiving all terminal I/O. This combined option would be useful for a Proto that operates as a central routing node, or as a simple node-to-node message exchange facility. Combining the two options during compilation will result in a small program, compared to the "normal" Proto program.

If the MONITOR is not removed, several places within the source code containing the macro TRACE can be activated by compiling with the option -OBTRACE. TRACE is a macro that uses the value of various MONITOR "trace" Flag variables to control the output of debugging information. For example, if -DEBUG was used during compilation, setting the MONITOR Flag variable "rtrace" will result in debug output from the "frouta()" net-layer process. By default, all trace output is disabled, so you must "Set" the Flags that are associated with the output you desire.

Several areas of the code use a modified version of the ASSERT macro to explicitly test for the truth of conditions. An ASSERT failure results in the Proto program aborting, along with an error message pointing to the failing assertion. Compiling with -ONDDEBUG will remove the assertion

tests, but this should be done only after thorough debugging of code changes.

Many of the alternative compiled versions of Proto can be generated using the "make" command and the supplied "makefile" file. See the front of "makefile" for all the possibilities. Enjoy!

*/

```

# Standard makefile for Proto.
# "make" defaults to NOT compiling the BTRACE code, whila compiling in the
# Window Manager (NOWM not specifiad) and the MONITOR (NOMONIT not specifiad).
# The output executabl is called "Proto".
# Other "Proto"s are generated by specifying the desired executable:
# make nwProto -- definas NOWM and BTRACE, doasn't usa Window Manager.
# maka nomonProto -- definas NOMONIT, lacks MONITOR process and variables.
# make tinyProto -- defines NOMONIT & NOWM, no Windows & single user (minimum).
# make tProto -- lika Proto but also defines BTRACE.
# (use this Proto for debugging)
# make all -- makes all of the above, one at a time.
#
# See README file for more information and version history
#
PROGRAMS = Proto nwProto nomonProto tinyProto tProto
PNAME = Proto
CDPTS = -D -I$(HOME)/CC/src/include -DBSO
# The "-I" is needed on some machinas that haven't officially installed
# the Concurrent C compiler package. The "-D" is only needed because
# both AT&T and UC @ Berkely consider the pre-defined #define variable
# called "unix" to be sufficient to make portable code possible. Tain't so!
# Thus, in order to distinguish the 2 "standard" systems, I have created a
# "ifdef BSO" capability to distinguish BSO-unix from SYSS-unix.

/* Simple-minded routing scheme for Network Layer. If "to" is in NodeIOS,
the routing is to ThisNode. Otherwise, look for a Link that has "to" as
the ID at the other end of the Link. Failing that, look for the first
Link that has "to" in it's "ids" string. The "dest_found" variable is
only to determine if "to" wasn't found at all (False) or was found only
on Links that were "down" (True). "last_ditch" is used to try all
routes to "to" that don't involve "inlink" before routing back over the
incoming Link.
NOTE: "to" == "from" where "inlink" is >= 0 (message in over a link)
is considered a 8edDast (because the current implementation of Proto
won't ever send a message out that's destined for itself), but this could
be changed if it was useful for verifying routing at the other end
of a Link or whatever....??

/* The FrameQE structure implements a doubly-linked circular queue as
an array of "FrameQE" elements. The "Head" of the queue is one element
of the array (not typically element 0) and an empty queue has the
"prev" and "next" items of the "Head" element both set to the index
of the "Head" element. The "tics" item is used only in the "Send0"
frame timer queue in 'foutput', but doesn't waste enough space to
justify another structure for the other queues. Queue elements are
manipulated by 2 functions: Insert() and Remove(). Insert() will
automatically Remove() an element from an existing list (if any)
before inserting it as a new element in "front of" another designated
element. Insert()ing in "front of" the queue "Head" places the new
element at the end of the queue.

(on TimerQ); if so, just reset "tics" to new interval, otherwise add HEAR to
TimerQ. If nothing is sent before the timer expires, a HEARtbeat frame will
be added to the SendQ, unless SendQ already has an entry.
Note: If HEAR is placed on SendQ and another frame is added to SendQ prior
to HEAR's transmission, HEAR will NOT be removed from SendQ (even though

```

```

having HEAR on SendQ with another frame is ..well.. redundant and
wasteful). This is a low probability situation, since it would imply HEAR
time-out and was entered on SendQ just before another SendQ entry was
made, but before framereq() could occur. To avoid sending HEAR in this
case (which hurts only throughput (?) on a previously idle channel), HEAR
could be thrown away at the beginning of framereq() IF SendQ has another
entry on it. [The code is provided above, but turned off.]
In time-out processing (ftime()), HEAR timeout is handled last to avoid
putting HEAR on SendQ and then adding another entry to SendQ as the result
of another type of time-out during the same entry to ftime().
*/

    wprintf(Lp->o,"%c DISC attempt fails\007\007\n",Lp->id);
}
} /* end "if( buffered ..." else case */
}
/* ----- ACK Timeout Processing ----- */
/* ACK is placed on the TimerQ when an incoming frame must be ACKed and there
are no entries on the SendQ. (SendQ entries all carry a piggyback ACK).
On time-out, ACK should be added to SendQ only
1) if SendQ is empty,
2) the Link is not in the DISC state (on transitions to DISC state, ACK is
not removed from TimerQ -- it eventually times out. No harm is done if
DISC state is entered and exited while ACK is timing out, since at most
it will cause an extra ACK to be transmitted.) and
3) no previous frame was sent with the current "ExpectedF-1" piggyback ACK.
This last condition is determined by the "last_ACK" variable, and can occur
only if another frame has not been added to SendQ and transmitted during the
time the ACK is on the TimerQ. Rather than having ACK removed from the
TimerQ every time another frame is removed from SendQ and transmitted, the
"last_ACK" variable records every piggyback ACK and just waits for time-out
to remove the ACK from TimerQ. (See "framein()" for details.)
*/
    if( timeout_ACK > 0 ) {
        if( SendEmpty() && last_ACK != ModDec(Lp->ExpectedF)

                timeouts -- handled by "framein()" when SendQ empty. */
        }
    }
/* ----- HEAR Timeout Processing ----- */
/* Put HEAR on SendQ if Link is CDNNected and SendQ is empty. If Link is in
any other state, either it's DISC (and HEAR shouldn't be sent) or other
timing (waitingDISC or waitingCDNN) will result in SendQ entries. When
the Link enters CONN, HEAR need not be added to TimerQ, since every entry
to the CONN state adds an entry to SendQ and "framereq()" will then start
HEAR timing when the SendQ is empty. Note that "framereq()" is the only
place where HEAR timing is initiated, since it most closely determines the
beginning of frame transmission and is the most reasonable point to start
timing for "idle channel". (HEAR time-out is processed last to minimize
the waste of adding HEAR and then another frame to SendQ as the result of
other time-out actions.)
*/

.TH PROTO 1 "17 December 1986"
.SH NAME
Proto \- Exercisa a Link-layer data transmission protocol
.SH SYNOPSIS
.B Proto
[-r] node-IDs [ link-IDs,comm-device ] ...
.SH DESCRIPTION
.I Proto
axarcises a Link-layer data transmission protocol implementation
written in Concurrent C.
The implementation has several possible interfaces to the user,
selectad at compilation time via '-O' options to the Concurrent C compiler.
These interfaces are determined by the presence or absence of the Window
Manager screen interface (part of the Concurrent C 'package') and
the presence or absence of the MONITOR interface.
The absence of the MONITOR causes all MONITOR input (see below) to
be unrecognized, and also results in the MONITOR not being created as
a process by
.IR Proto .
See the README file for more information on the compilation options.
.PP
In general, the variously compiled versions of Proto are namad as follows:
.ta 13
\fBProto\fP has Window Manager and MONITOR, but no TRACE lines compiled.
\fBtProto\fP like \fBProto\fP, with TRACE lines compiled for testing.
\fBtinyProto\fP no Window Manager or MONITOR, single User process.
\fBnwProto\fP no Window Manager or Users, has MONITOR
\fBnmonProto\fP no MONITOR, has Window Manager and 2 Users
.fi
.br
The '\fB-r\fP' option is only valid with '\fBtinyProto\fP' and '\fBtinyProto\fP'.
It's appearance (immediatly following '\fBProto\fP') will cause '\fBProto\fP'
to place all normal terminal output (error messages, etc.) into a file
named "Proto-stdout".
The is primarily useful with the ''\fIcomm-device\fP' capability (see below).
.PP
The
.I node-IDs
is a string of alphanumeric characters; the first character becomes the
"naame" of this '\fBProto\fP' node, and any other characters become aliases
for this node.
.PP
The
.I
link-IDs,comm-device
arguments each describe a Link (a Link-layer set of processes connected to a
peer set of process over the
.IR comm-device interface).
.PP
The
.I link-IDs
era specified in the same manner as
.IR node-IDs .
The first identifier is taken as the name of the node at the other end
of the Link.
The other identifiers are nodes that are also connected to the other end.
The Link selection algorithm will select, whera possible, a Link directly
connected to a node, if the Link is "up and working". Otherwise, the
first "up and working" Link with the requested
.I node-name
in its list of
.I link-IDs
will be used.
.PP
.I Comm-device
is opened by
.B Proto
```

with an input file descriptor and an output file descriptor.
 Link-level output is placed on the output file descriptor and link-level input is read from the file-descriptor.

The "special"

.IR comm-device s
 currently supported are the 'pipe', the 'cmd' and the 'tty'.

The 'pipe' forms an internal "loop-around" connection between the input and output of the specified Link.

Any output is just echoed back as input (useful for quick tests?).

.PP
 The 'cmd' causes \fBProto\fP to fork(2) and execv(2) a new shell(see sh(1)) arranged such that typed input is sent to the shell, and output from the shell is echoed back to the user.

After the user has started whatever processes desired using shell commands, a line of input (currently "ENO-LEVI") tells \fBProto\fP that the usual link-level I/O can now occur to the executing "commands".

The "commands" should use file descriptor 0 to read link-level output from \fBProto\fP and file descriptor 1 to send responses back to \fBProto\fP.

.PP
 The 'tty' causes \fBProto\fP to use file descriptor 0 for this Link's input and file descriptor 1 for it's output.

Since \fBProto\fP will start using this immediately, it should always appear as the last \fIlink-IOS,comm-device\fP argument.

.PP
 Any

.I comm-device
 name other than the "special" ones above are assumed to be of the form

.I device-name
 or
 .IR device-name1,device-name2 .

The latter form will cause \fBProto\fP to open(2) \fIdevice-name1\fP for reading and \fIdevice-name2\fP for writing.

Link-level output for this Link will be directed to \fIdevice-name2\fP and input will be read from \fIdevice-name1\fP.

If the "non-comm" form of \fIdevice-name\fP is used, it is opened for both input and output, and all link-level I/O is done through it.

.PP
 As an example,

.br
 .sp
 .nf

```
nwProto -r FARM b12,p1pa c3b2,/dev/tty03 rich,tyt
```

.sp
 .fi

would set up the "nodeIO" as 'F' with 'A', 'R', and 'M' as aliases for 'F'. Three Links would be set up, one named 'b' that is connected to a node named 'b' that in turn claims to also be connected to other nodes named '1' and '2'; actually, as a 'pipe', all output is just echoed back.

The Link named 'c' could send/receive messages using /dev/tty03; link 'c' would handle messages to nodes 'c', '3', 'b' and '2'.

Messages to node '2' would attempt to route over the Link to node 'b' if 'b' is "up and working", otherwise node 'c' would be attempted.

Messages to node 'c' itself would route to node 'b' if the Link to node 'c' was not "up and working", or to node 'r' if both 'b' and 'c' were not "up and working".

Link 'r' would actually use file descriptors 0 and 1 for I/O, so the whole \fBProto\fP command should be executed from another invocation of \fBProto\fP, probably using the 'cmd' capability.

.SH NO WINDOW MANAGER

This interface results in a single 'user' process with access to the terminal. All input is directed to the 'user' process, and all user-level output is directed to "stdout".

Error output is directed to both "stdout" and "stderr", which may be re-directed by the

```
IR sh (1)
"2>" syntax when
.I Proto
is invoked.
.PP
```

Input to the 'user' is handled by examining the first character of each input line.

The action taken for particular characters is:

```
.nf
.ta 9
Character      Action
^O (EOF)      Terminate 'user' process.
/             Terminate 'user' process.
+x           Send CONNECT request to Link 'x' processes.
\ -x         Send DISCONNECT request to Link 'x' processes.
*           Send characters following '*' out on all CONNECTED Links.
           (This "Broadcast" capability is currently unimplemented.)
%           Send all characters from the filename following '%'.
           (Also currently unimplemented.)
```

```
.sp
```

```
.fi
```

Otherwise, the first input character is assumed to be a

```
.I link-ID
```

```
and
```

```
.B Proto
```

will attempt to find an appropriate Link over which to send the message (characters following the

```
\_IR link-ID).
```

```
.SH MONITOR
```

The 'MONITOR' process accepts all 'User' input and commands (and is considered User 0 by other processes), but in addition can accept some other commands.

These are currently:

```
.nf
```

```
.ta 9
```

```
Command Action
```

```
~X      Abort all \fBProto\fP processes, restore TTY characteristics.
~Mx     Enter the "monvar" interface mode. This allows access to MONITOR
        variables for the Link named 'x'. Exit the mode with a 'Q'.
```

```
.sp
```

```
.fi
```

```
.PP
```

The "monvar" interface allows access to "MONITOR variables" that control TRACE output and data collection during execution. The interface commands are:

```
.nf
```

```
.ta 9
```

```
Command Action
```

```
Q       Exit "monvar" interface mode.
d var   Display all MONITOR variables and their values.
v var   Display value of MONITOR variable named "var".
s var   Set MONITOR variable "var" to 1.
r var   Set MONITOR variable "var" to 0 (i.e., "reset").
```

```
.sp
```

```
.fi
```

Further information on the use and usefulness of the MONITOR variables is contained in the \fBProto\fP README file.

```
.SH DIAGNOSTICS
```

Diagnostics are, hopefully, self explanatory.

```
.sp
```

When \fBProto\fP is started, the list of "escaped" character codes (in octal) is printed, along with the corresponding character (in octal) what will be used as a replacement.

```
.SH BUGS
```

The user interface is fairly crude, but it allows sufficient access for tracing and debugging of the protocol.

If the Window Manager interface is used and

```
.B Proto
```

is killed, the "tty" interface will usually not be restored.

```
Try:
```

```
.br
```

```
.sp
```

```
.TP 10
```

```
stty -raw -cbreak echo
```

```
.br
```

.SP
to restore most functionality.

.PP

The set of MONITOR variables is probably not correct for total prove-in of the protocol implementation, since they were invented as needed during the implementation.

**THE ANALYSIS AND EXTENSION OF
AN EXISTING DATA LINK PROTOCOL**

by

ALAN LEON VARNEY

B. S., Kansas State University, 1970

AN ABSTRACT OF A MASTER'S REPORT

**submitted in partial fulfillment of the
requirements for the degree**

MASTER OF SCIENCE

Department of Computer Science

Manhattan, Kansas**

1987

**The analysis and Extension of
an Existing Data Link Protocol**

by Alan L. Varney

An Abstract of a Master's Report

This report presents a data link protocol designed by analyzing protocols in the literature, choosing one as a base and extending that base with mechanisms taken from other protocols. The extended protocol is described in some detail. Time sequence diagrams are used to demonstrate the operation of the protocol under several transmission failure conditions.

An implementation of the protocol in Concurrent C is also presented. A test environment that provides monitoring and selective control over the implementation is described.
