INTRODUCTION

The purpose of this thesis was to devise an efficient approach to water resource control optimization. A test system has been devised and solved within an analytical framework.

This study concerns optimal policies regulating water resource structures already in existence. The majority of work in this field is directed toward simulation. Physical and regulatory system models are executed on a trial and error basis. The results of these runs are analyzed to determine optimal combinations. The techniques of simulation in this field are fully illustrated in texts written by Emery Castle (1), and Maynard Hufschmidt (2). With regard to resource control policies, an analytical approach has been proposed whereby objective functions may be constructed and solved directly. A definite need is recognized here since the installation of expensive structures may be eliminated by the efficient use of what is currently available.

When constructing the model for a test system, particular attention must be devoted to water supply, water demand, and the measures available for meeting these demands. The major elements of water supply are a part of surface and ground water flow as well as natural storage. Relevant characteristics are quantity, quality, and availability measured with respect to time and location. Water demands are points or
zones (present or potential) which draw upon the water resources of the system (2). Examples would include

a. Municipal and industrial water supply.
b. Hydroelectric power needs.
c. Irrigation.
d. Flood control.
e. Water quality.
g. Water based recreation.

Measures for meeting these demands and alleviating water problems would include such examples as

a. Multi-purpose reservoirs.
b. Hydroelectric power plants.
c. Irrigation canals.
d. Water transmission and diversion works.
e. Waste treatment facilities.

An initial model has been proposed and developed for study. A sketch of the physical system is illustrated in Figure 1. In constructing this model, data was drawn from the literature wherever possible. This practice was adopted to insure realistic response behavior. In addition, this data is in a form which subsequently may be determined for the analysis of real water resource systems.
Fig. 1. Example of a water resource control system.
The basis of study for the model evolves about a form of static economic analysis. Assumptions made in this analysis are listed below.

a. All capital facilities have been installed prior to the period of analysis.

b. Target outputs remain fixed constants (or periodic functions) during the period of analysis. Target outputs represent minimal water supply commitments below which economic losses are suffered by a particular source of demand.

c. Analysis shall be based on a stage-wise or finite difference approach. For the system in question, one month constitutes a single stage or increment of time.

d. Total benefits accrued during one increment of time, less total economic losses or penalties, less operating and maintenance costs contracted during the same period of time and discounted to present value, constitutes the "cash-flow" for this period.

e. The object of this study is to determine that set of operational policies which maximizes the cash flow stream over the period of economic analysis (3).
CONSTRUCTION OF A SYSTEM MODEL

WATER FLOW DISTRIBUTION

As illustrated in Figure 1, optimal policies for the system will affect water storage and releases for

a. Municipal and industrial water supply.
b. Hydroelectric power needs.
c. Irrigation.
d. Recreation.

Water input to the system occurs from

a. Bulk flow from the river.
b. Ground water.
c. Precipitation.
d. Drainage from the basin.

Water output from the system occurs from

a. Bulk flow from the river.
b. Ground water.
c. Evaporation.
d. Transpiration.

System accumulation occurs from

a. Absorption.
b. Consumption ($I_p$).

With regard to the system in question, two assumptions are made to achieve some simplification. First, the loss from the system by evaporation and transpiration is equal to the gain by precipitation. Secondly, ground water effects are to be considered negligible.

The nature of water flow into a system during the period of analysis may be approximated with a hydrology generator. This is a mathematical model (either deterministic or stochastic in nature) which predicts future flow characteristics on the basis of past records and meteorological forecasts. A deterministic model could express water inflow as an explicit function of time and location. Under these circumstances, it may be proposed that a set of optimal policies be determined for the economic life of the system, and then re-determined at the end of each stage with the consequent updating of the hydrology generator. For this system then, the success of water allocation policies for a given month would depend upon the accuracy of the hydrology prediction made at the beginning of that month.

To account for the seasonal fluctuations of water flow, a Fourier series representation of the hydrology generator has been considered. A simplified version could be of the finite form
\[ X_Q^{(n)} = q_o + A \sin(\omega n) + B \sin(\omega' n) \]  

where

\begin{align*}
X_Q^{(n)} &= \text{Flow rate of water into the system during stage } n, \text{ acre ft./mo.} \\
q_o &= \text{Mean rate of flow, acre ft./mo.} \\
\omega &= \text{A frequency factor of short term fluctuations, cyc./mo.} \\
A &= \text{Expected deviation of short term fluctuations, acre ft./mo.} \\
\omega' &= \text{A frequency factor of long term fluctuations, cyc./mo.} \\
B &= \text{Expected deviation of long term fluctuations, acre ft./mo.}
\end{align*}

An advantage of a Fourier series expression is that it may be expanded to describe situations as complex as the programmer feels necessary. Flow data used for the model in this paper was obtained from a report by the U.S. Corps of Engineers (5). The form of this data is presented in Table 1. It was taken from the Jordan Creek area, a part of the Delaware River Basin. Observations were taken over a period of several years, and then tabulated statistically on a twelve month basis. The table may be approximated by the expression

\[ X_Q^{(s)} = 7.0 \times 10^3 + 5.0 \times 10^3 \sin(\pi n/6) + 1.0 \times 10^3 \sin(\pi n/60) \]

The output of the hydrology generator in equation 2 is illustrated in Figure 1.1 for a time period of twelve months.

**BENEFIT AND LOSS FUNCTIONS**

As mentioned earlier, system analysis concerns the effect of operational policy on the monetary benefits and consequences accrued by each demand zone. Consequently, functions must be derived for each source of demand, relating economic gains or losses as a function of scheduled releases within the system.

For a given resource output, each point from a benefit function should measure the lesser of the following two commodities.

a. The resource cost of providing equivalent goods and services by the least costly alternative.

b. The "willingness" of consumers to pay for these goods and services.

The technique of constructing a benefit function for a given demand zone is illustrated in Figure 2. Each point from an economic loss function should measure the penalty of failure to meet a given target output. The target output for this demand source represents a minimal supply commitment. Failure to meet this commitment will invoke losses or penalties against the

system. Examples of resource outputs with associated gain and loss functions are listed below (6).

a. Municipal and industrial water supply at the time and location of need.

b. Reservoir supply for hydroelectric power.

c. Reservoir use for recreation.

d. Water supply for irrigation.

On the pages that follow, benefit and economic loss functions are expressed for each demand source considered in the test system.

Water Supply For Urban Needs

Urban requirements include water supply for domestic, public, and commercial use. Some of the costs which must be faced involve storage, transport, purification, and administration (7). The marginal price of water in the Jordan Creek area has been found equal to $12.10/acre foot under normal load conditions (5). This value would correspond to a single point on the demand schedule illustrated in Figure 2. In many cases, this may be the only information obtainable. If this is the case, the benefit function may be approximated by a straight line as shown in Figure 3. If, however, cost information is
Fig. 3. A benefit function for urban water supply & quality.
available for varying load conditions, the benefit function would be plotted as a curve of the nature also shown in Figure 3. With this information given, a programmer can use a device such as Lagrange's Formula to fit data with an expression. The curve used in Figure 3, for example, is approximated by the function

\[
\phi_{UB}^{(n)} = -4.0 \times 10^{-4} (\theta_{UR}^{(n)})^2 + 1.4 \times 10^{-1} \theta_{UR}^{(n)}
\]  

(3)

where

\[
\phi_{UB}^{(n)} = \text{System benefit accrued from water supply to urban areas during stage } n, \text{ dollars/mo.}
\]

\[
\theta_{UR}^{(n)} = \text{Scheduled release of water for urban use during stage } n, \text{ acre ft./mo.}
\]

The unit loss sustained from unexpected deficiencies below the target output demand has been found equal to $16.40/acre foot (5). Data for loss functions will, at the very least, be more difficult to obtain than that for benefit functions. Values here are connected with commercial and private losses contracted in a community when minimal expected commitments are not met. Average or point values such as the one above should, in most cases, be expected (2). Penalty or loss functions would, therefore, be linear. An example of such a function is
shown below.

\[
\Phi_{UL}^{(n)} = 1.64 \times 10^4 (\chi_{UT}^{(n)} - \theta_{UR}^{(n)}) = 0, \quad \chi_{UT}^{(n)} \leq \theta_{UR}^{(n)}
\]  

(4)

where

\(\Phi_{UL}^{(n)}\) = Loss sustained from urban supply shortage below the target output demand for stage n, dollars/mo.

\(\chi_{UT}^{(n)}\) = Urban target output demand during stage n, acre ft./mo.

For the urban center in question, a constant target demand of \(2.25 \times 10^3\) acre feet/month has been found a good approximation. It will be noted that the unit penalty cost is greater in magnitude than a corresponding decrease in the benefit function. The loss from an unanticipated deficit for an existing system will always be more costly than a reduction in planned output (8).

Water Supply For Irrigation

Under normal operating conditions in the Jordan Creek area, the marginal price of water for irrigation is \$2.25/acre foot (5). This is under urban supply costs since less is required
in purification and distribution facilities. An example of a benefit function is shown in Figure 4. This curve illustrates the connection between system gains and scheduled water releases for irrigation. Using Lagrange's Formula, the curve may be approximated by the following expression.

\[
\phi_{IB}^{(n)} = -8.0 \times 10^{-5} (\theta_{IR}^{(n)})^2 + 2.7 \theta_{IR}^{(n)}
\]  

(5)

where

\[
\phi_{IB}^{(n)} = \text{System benefit accrued from irrigation during stage } n, \text{ dollars/mo.}
\]

\[
\theta_{IR}^{(n)} = \text{Scheduled release of water for irrigation during stage } n, \text{ acre ft./mo.}
\]

The unit loss sustained from unexpected deficiencies below the target output demand has been found equal to $3.42/\text{acre foot}$ (5). A linear function expressing accrued loss as a function of this deficiency is shown below.

\[
\phi_{IL}^{(n)} = 3.42 (\chi_{IT}^{(n)} - \theta_{IR}^{(n)})
\]

\[
= 0, \quad \chi_{IT}^{(n)} \leq \theta_{IR}^{(n)}
\]

(6)

where
Fig. 4: A benefit function for irrigation water supply.
\( \phi_{IL} \) = Loss sustained from irrigation supply shortage below the target output demand for stage \( n \), dollars/mo.

\( X_{IT}^{(n)} \) = Irrigation target output demand during stage \( n \), acre ft./mo.

Unlike the urban center under study, the target output demand for irrigation can fluctuate widely from season to season. However, since the water supply needs of agriculture are cyclic in nature, target output demand may be expressed as a periodic function without encroaching into the field of dynamic analysis. A suggested form of this function is shown below.

\[
X_{IT}^{(n)} = d_o + D \sin(\omega' n)
= 2.25 \times 10^3 + 1.0 \times 10^3 \sin(\pi n/6) \quad (7)
\]

where

\( d_o \) = Mean flow rate required by the irrigation target output demand, acre ft./mo.

\( \omega' \) = A frequency factor of seasonal fluctuations, cyc./mo.

\( D \) = Expected deviation of seasonal demand fluctuations, acre ft./mo.

Water Supply For Hydroelectric Power

Regarding power distribution within the test system, two
assumptions are made. First, hydroelectric power which is produced within the system is used by demand zones within the system. Power is not transported to other areas. Secondly, the widely fluctuating nature of water movement eliminates hydroelectric power as a continually reliable source. Consequently, when power demands cannot be met internally, it is tapped from an external network. Common to the study of most areas, are relations which express unit benefits as a function of the hydroelectric plant output. Such a relation is plotted in Figure 5 for a power plant at one of the Jordan Creek reservoirs (5). Using Lagrange's Formula, this curve may be approximated by the function

\[ \phi_{\text{UnB}}^{(n)} = 3.07 \times 10^{-16} (\phi_{\text{po}}^{(n)})^2 - 4.0 \times 10^{-9} (\phi_{\text{po}}^{(n)}) + 1.71 \times 10^{-2} \]  

(8)

where

\[ \phi_{\text{UnB}}^{(n)} = \text{Unit benefit from hydroelectric power output during stage } n, \text{ dollars/kw. hr.} \]

\[ \phi_{\text{po}}^{(n)} = \text{Average output of the power plant during stage } n, \text{ kw. hrs./mo.} \]

\[ \phi_{\text{IB}}^{(n)} = \text{benefits accrued during the } n^{th} \text{ month or stage from hydroelectric power, is then equal to} \]
Fig. 5. Unit hydroelectric power benefits as a function of plant output.
\[ \phi_{HB}^{(n)} = \phi_{UnB}^{(n)} x_{po}^{(n)} \]  

(9)

To facilitate a solution later in the analysis, it is desirable that all functions be expressed in terms of water movement and time. With reference to the reservoir mentioned above (5), the power variable, \( x_{po}^{(n)} \), is related to "head" (reservoir height at the dam), and water flow rate through the turbines by the expression

\[ x_{po}^{(n)} = K \cdot e \cdot x_{TR}^{(n)} x_{h}^{(n)} = 8.74 x_{TR}^{(n)} x_{h}^{(n)} \]  

(10)

where

\[ K = \text{A conversion factor relating hydroelectric power output to system parameters, k.w. hrs./acre ft.}^2 \]

\[ e = \text{A plant efficiency factor.} \]

\[ x_{TR}^{(n)} = \text{Average flow rate utilized for the production of hydroelectric power during stage n, acre ft./mo.} \]

\[ x_{h}^{(n)} = \text{Average head during stage n, ft.} \]

The stream diverted through power turbines, \( x_{TR}^{(n)} \), is defined explicitly in the expression below.
\[ x^{(n)}_{TR} = \theta^{(n)}_{UR} + \theta^{(n)}_{IR} + \theta^{(n)}_{ER} - \theta^{(n)}_{TB} \]  

(11)

Where:

\[ \theta^{(n)}_{ER} = \text{Scheduled release of water in excess of } \theta^{(n)}_{UR} \text{ and } \theta^{(n)}_{IR} \text{ during stage } n, \text{ acre ft./mo.} \]

\[ \theta^{(n)}_{TB} = \text{Water flow from the reservoir which cannot be utilized for hydroelectric power, acre ft./mo.} \]

\[ \theta^{(n)}_{TB} \] is, in effect, a slack variable. It permits the imposition of constraints on the power output level without affecting the other decision variables. Head, \( x^{(n)}_h \), may in turn be described as a function of reservoir contents. Such an expression must be determined empirically. An example of such work is illustrated in Figure 6. Using Lagrange's Formula to fit this plot, approximation is made possible by the quadratic function

\[ x^{(n)}_h = -6.70 \times 10^{-9} (x^{(n)}_v)^2 + 1.97 \times 10^{-3} (x^{(n)}_v) \]  

(12)

Where:

\[ x^{(n)}_v = \text{Average reservoir volume during stage } n, \text{ acre ft.} \]

Combining equations 8, 9, 10, and 12, \( \theta^{(n)}_{RB} \) may be expressed solely in terms of \( x^{(n)}_v \) and \( x^{(n)}_{TR} \).
Fig. 6. Head vs. reservoir contents.
\[
\delta_{\text{HB}}^{(n)} = -6.10 \times 10^{-42} \left( x_v^{(n)} \right)^6 \left( x_{\text{TR}}^{(n)} \right)^3 + 5.40 \times 10^{-36} \left( x_v^{(n)} \right)^5 \left( x_{\text{TR}}^{(n)} \right)^3 \\
-5.40 \times 10^{-29} \left( x_v^{(n)} \right)^4 \left( x_{\text{TR}}^{(n)} \right)^3 - 1.37 \times 10^{-27} \left( x_v^{(n)} \right)^4 \left( x_{\text{TR}}^{(n)} \right)^2 \\
+1.56 \times 10^{-23} \left( x_v^{(n)} \right)^3 \left( x_{\text{TR}}^{(n)} \right)^3 + 8.00 \times 10^{-20} \left( x_v^{(n)} \right)^3 \left( x_{\text{TR}}^{(n)} \right)^2 \\
-1.18 \times 10^{-14} \left( x_v^{(n)} \right)^2 \left( x_{\text{TR}}^{(n)} \right)^2 - 1.00 \times 10^{-11} \left( x_v^{(n)} \right)^2 \left( x_{\text{TR}}^{(n)} \right)^1 \\
+2.90 \times 10^{-14} \left( x_v^{(n)} \right) \left( x_{\text{TR}}^{(n)} \right)^1 
\] (13)

\( x_v^{(n)} \), in addition, may be expressed in terms of flow variables by running a material balance about the reservoir. In continuous form, the rate of accumulation would be equal to the flow rate of water into the reservoir less the flow rate leaving. In finite difference form, this balance is represented by the transformation function that follows.

\[
\begin{align*}
\hat{x}_v^{(n)} &= \hat{x}_v^{(n-1)} + \alpha_q - \alpha_{\text{TOT}} \\
&= \hat{x}_v^{(n-1)} + \alpha_{\text{TOT}} - \delta_{\text{UR}}^{(n)} - \delta_{\text{TR}}^{(n)} - \delta_{\text{ER}}^{(n)} 
\end{align*}
\] (14)

where

- \( \hat{x}_v^{(n-1)} \) = Average reservoir volume during stage n-1, acre ft.
- \( \hat{x}_v^{(n)} \) = Total flow rate of water released from the reservoir during stage n, acre ft./mo.

The unit loss sustained from unexpected deficiencies below the target output demand has been found equal to $0.02/k.w. hr.
A linear function expressing accrued loss as a function of this deficiency is shown below.

\[ \phi_{HL}^{(n)} = 2.0 \times 10^{-2} (x_{HT}^{(n)} - x_{po}^{(n)}) \]

\[ = 0, \quad x_{HT}^{(n)} \leq x_{po}^{(n)} \]  \hspace{1cm} (14)

where

\[ \phi_{HL}^{(n)} = \text{Loss sustained from a power shortage below the target output demand for stage } n, \text{ dollars/mo.} \]

\[ x_{HT}^{(n)} = \text{Target output demand for hydroelectric power during stage } n, \text{ k.w. hrs./mo.} \]

For the test system under study, a constant target output demand of \(5.0 \times 10^6\) k.w. hours/month has been found a good approximation. Again, since \(\phi_{HL}^{(n)}\) must be expressed in terms of flow variables,

\[ x_{po}^{(n)} = f(x_{TR}^{(n)}, x_{V}^{(n)}) \]

\[ = K e^{x_{TR}^{(n)} x_{n}^{(n)} x_{V}^{(n)}} \]

\[ = -5.85 \times 10^{-2} (x_{V}^{(n)})^2 (x_{TR}^{(n)}) + 1.7 \times 10^{-2} (x_{V}^{(n)}) (x_{TR}^{(n)}) \]  \hspace{1cm} (15)

Combining equations 14 and 15, \(\phi_{HL}^{(n)}\) may be expressed in terms of \(x_{V}^{(n)}\) and \(x_{TR}^{(n)}\).
\[ \phi_{HL} = +1.17 \times 10^{-9} (x_{V})^2 (x_{TR}) - 3.4 \times 10^{-4} (x_{V}) (x_{TR}) + 2.9 \times 10^{-2} (x_{HT}) \]

\[ = 0, \quad x_{HT} \leq f(x_{TR}, x_{V}) \]  \hspace{1cm} (16)

Water Supply For Recreation

Water based recreation would include such activities as boating, swimming, and fishing as well as interest in adjacent shore facilities (9). The cost of alternative services has been calculated at \$1.05/visitor-day for the Jordan Creek area (5). The Corps of Engineers, in addition, has discovered that attendance may be plotted empirically as a function of reservoir capacity. An example of such a relationship is illustrated in Figure 7 for the Jordan Creek area. Using an appropriate curve fitting technique, Figure 7 may be approximated by the equation

\[ x_{RA}^{(n)} = +1.53 \times 10^{-9} (x_{V})^2 - 3.68 \times 10^{-4} (x_{V}) + 3.89 \times 10^1 \]  \hspace{1cm} (17)

where

\[ x_{RA}^{(n)} = \text{Attendance for water based recreation during stage } n, \text{ visitor-days/acre of reservoir surface/month).} \]

In a similar manner, the reservoir surface area, \( x_{RS}^{(n)} \), may be plotted against its capacity. With this relationship known, system gains from recreational activities may be expressed as
Fig. 7. Attendance as a function of reservoir capacity.
a function of $x_v^{(n)}$.

$$\phi_{RB}^{(n)} = 1.05 \frac{x^{(n)}_{RA}}{x_v} \frac{x^{(n)}_R}{x_v} \frac{x^{(n)}_S}{x_v}$$

$$= 3.2 \times 10^{-10} (x_v^{(n)})^3 - 7.70 \times 10^{-5} (x_v^{(n)})^2 + 8.1 \times 10^{-6} (x_v^{(n)})$$  \hspace{1cm} (18)

where

$\phi_{RB}^{(n)}$ = System benefit accrued from water based recreation during stage n, dollars/mo.

For this system, no target output or associated loss function is connected with recreation.

ECONOMIC ANALYSIS

As stated earlier, the object of a system analysis is to determine that set of operational policies which maximizes the cash flow stream over the period of analysis. Assuming an estimated economic life of Y years, this goal may be stated symbolically as follows.

$$\text{Maximize } V = \sum_{n=1}^{12Y} \frac{(S^{(n)})}{(1 + r)^n}$$  \hspace{1cm} (19)

where
\[ V = \text{The present value of net system gains accrued during the period of economic analysis, dollars.} \]

\[ S^{(n)} = \text{The net economic gain accrued by the system during stage n, dollars.} \]

\[ r = \text{The interest rate of money prorated on a monthly basis.} \]

\[ S^{(n)} \text{ in turn, may be represented by the expression} \]

\[ S^{(n)} = T^{(n)}_B - T^{(n)}_P - T^{(n)}_{om} \tag{20} \]

where

\[ T^{(n)}_B = \text{Total benefit accrued by the system during stage n, dollars.} \]

\[ = \phi^{(n)}_{UB} + \phi^{(n)}_{IB} + \phi^{(n)}_{HB} + \phi^{(n)}_{RB} \tag{21} \]

\[ T^{(n)}_P = \text{Total penalty or loss contracted by the system during stage n, dollars.} \]

\[ = \phi^{(n)}_{UL} + \phi^{(n)}_{IL} + \phi^{(n)}_{HL} \tag{22} \]

\[ T^{(n)}_{om} = \text{Total operating and maintenance costs contracted by the system during stage n, dollars.} \]

As the objective function, equation (19) is subject to the following set of constraints.
a. \( 0 \leq \theta_{UR}^{(n)} \leq 4.0 \times 10^3 \)  

b. \( 0 \leq \theta_{IR}^{(n)} \leq 4.0 \times 10^3 \)  

c. \( \theta_{ER}^{(n)} \geq 1.0 \times 10^3 \)  

d. \( \theta_{UR}^{(n)} + \theta_{IR}^{(n)} + \theta_{ER}^{(n)} \leq 1.3 \times 10^4 \)  

e. \( \theta_{TB}^{(n)} \geq 0 \)  

f. \( \frac{X_{po}^{(n)}}{X_{TR}^{(n)}, X_{V}^{(n)}} \leq 7.2 \times 10^6 \)  

g. \( 2.0 \times 10^4 \leq X_{V}^{(n)} \leq 1.40 \times 10^5 \)  

These constraints represent physical boundaries or limitations which must be observed within the system. Constraints a and b, for example, represent points beyond which benefits will not occur for an increase in available water supply. These limits define the maximum capacities of transport and purification systems as well as the demand zones they service. Constraints c and d are limitations imposed on systems to ensure that water flow remains within the limits of existing river beds and channels. Constraint f represents an upper limit for the hydro-electric power plant. It is a reflection of physical size. Beyond this point, the plant can produce no more power, regardless of head or flow available. Constraint g defines the usable limits of the reservoir. The lower limit represents dead storage allocation for silting, and the accumulation of debris.
The upper limit represents the maximum capacity of the reservoir.

The control policies developed in this model are, in effect, rules for storing, releasing, and routing water through the system. In general, control policies affecting urban water supply, irrigation, and power generation conflict with flood control. Drawdowns for all of these purposes conflict with the maintenance of reservoir levels for recreational use. If it were not for these conflicts, there might possibly be little if any problem to consider. This study is orientated toward optimal water resource distribution with reference only to economic and physical considerations. If value judgments based on political or other frames of reference are inherent, additional priorities or constraints may be added to the model.

The objective function expressed in equation (19) relates net economic gains accrued by the system as a function of regulatory or operational policies. These policies affect flow releases from the reservoir during each increment of time, in this case, one month. For the system under study, four decision variables must be changed with time in such a way as to maximize the cash flow stream. For an analysis covering a period of \( Y \) years, the objective function would involve \( 4 \times 12 \times Y \) independent variables subject to the seven inequality constraints listed in equations (23) through (29). The size
of such a function would be formidable were it not for such techniques as dynamic programming. As a result, this function may be divided into a series of stage-wise problems, each involving four decision variables subject to the constraints listed above.
DISCUSSION OF RESULTS AND CONCLUSIONS

The objective function developed in the system model consists of four decision variables, \( \theta_{UR}^{(n)} \), \( \theta_{IR}^{(n)} \), \( \theta_{ER}^{(n)} \), and \( \theta_{TB}^{(n)} \), and one state variable, \( \dot{X}_V^{(n)} \), applied at each of \( N \) stages. Solution, it was discovered, fell naturally in the realm of dynamic programming. A computer program was constructed which tied all subroutines into a dynamic program routine as center. A complete discussion of this program is included in Appendix A. In addition, a set of directions is included for anyone wishing to use this program, or an extended version of it. At each stage in the dynamic program routine, a search was conducted for an optimal set of variables which influenced the policies set at that stage. This was accomplished by the Hooke and Jeeves pattern search technique. The search subroutine was modified somewhat, so that it could handle constrained problems. A discussion of the Hooke and Jeeves technique is included in Appendix B.

In Appendix C, results are given for work directly related to the computer program. This includes flow diagrams, listings, and an explanation of all symbols used in the program. In addition, a sample solution is printed in table form for a twelve stage problem. With output data in this form, the user may select an initial (or final) state variable, \( \dot{X}_V^{(n-1)} \), from a list of grid values, and then trace an optimal path relating control
policies against time. The size of the list found in these tables is controlled by input parameter cards. The size, and hence the accuracy may be varied to fit the needs of the problem. An initial state variable \( (\gamma(0) = 4.55 \times 10^{14} \text{ acre ft.}) \) was chosen arbitrarily, and an optimal path plotted from these tables. Appendix D illustrates the nature of this path as it ranges through a time period of twelve months. The variation of the state variable as well as the decision variables are included in these plots. The system model was developed with the idea that it could be modified or extended to cover different situations. Consequently, the dynamic program routine and the search subroutine were written in as general a manner as possible. They can, if desired, be utilized by completely separate model and constraint subroutines.

To save time on the computer, a price must be paid in terms of precision. Computational accuracy may be adjusted in two ways for this program. First, instructions may be inserted, directing the use of double precision. By doing so, the computer will round off values to 16 rather than the usual 8 significant figures. This will help prevent round off error from affecting calculated results. A great number of calculations were made in this program. Double precision could not be used, however, since it increased execution time by a factor of 5. One half hour was required for the normal
execution of a 12 stage problem. Interpolation error may be reduced by increasing the list of grid values for the state variable. To minimize time, a list size of 10 elements was chosen for the sample output illustrated in this work. The magnitude of the range determined for the state variable should warrant a larger grid network. Time limitations, however, made this impractical.

Modifications were made in the Hooke and Jeeves search subroutine such that perturbations were checked against existing constraints as well as the profit function. In spite of this feature, the search pattern would hang up on certain constraints. Unable to back up sufficiently to find a new approach, the search would terminate at a point short of a global optimum. Changing the form of one of the constraints appeared to alleviate this condition. The nature of the problem is such, however, I must conclude that the best possible values have not been found. At this time, I do not recommend a pattern search for constrained problems. A random search technique, on the other hand, would be quite useful since it can not be thwarted by a set of constraints. It does not lay patterns which can be terminated short of the desired optimum.
DISCUSSION OF TOPICS FOR FUTURE RESEARCH

The system model constructed in this paper is a beginning only. It can be modified and extended to cover many different situations. If greater complexity is desired for future research, several changes may be considered. The number of resource demand zones, for example, can be expanded. Flood control and navigational requirements may be added to those already under study. Flood control should be thought of as a special case since time-movement studies are concerned with a period of hours and days as opposed to the general case of months and years. A special hydrology generator must be developed to handle this situation.

The system considered in this work was centered about a single multipurpose reservoir, and required one state variable, \( X^m_v \), in the objective function. System models may include several reservoirs located in series or on separate tributaries. Several state variables will be involved. Special techniques such as quasi-linearization will be required to expedite a solution by dynamic programming.

In addition to varying the complexity of a system model, the mode of analysis may also be changed. In this paper, the system was stable and a form of static economic analysis employed. The assumptions made in this analysis have already been
listed. If the system is not stable, that is, continually growing, dynamic analysis should be considered. In addition to conditions already discussed, it would provide for capital facilities which may be installed anytime during the period of analysis. In addition, the corresponding target output demand levels can also be changed.

There is also no reason why a model must be deterministic in nature. It may also be stochastic. For those who are interested in this approach, serious consideration should be paid to the Markov model postulated by M. B. Fiering (2). This is a statistical expression of the hydrology generator as shown below.

\[ x_{i+1} = \mu_j + \theta_j (x_i - \mu_{j-1}) + t_{i+1} \sigma_j (1 - \rho_j^2)^{1/2} \quad (30) \]

where

- \( x_{i+1} \) = Estimated value of flow in the \((i+1)^{st}\) unit of time.
- \( \mu_j \) = Mean flow in the \(j^{th}\) season.
- \( x_i \) = Flow in the \(i^{th}\) unit of time.
- \( \theta_j \) = Regression coefficient of flow in season \(j\) on flow in season \((j-1)\).
- \( \rho_j \) = Correlation coefficient between flows in seasons \(j\) and \((j-1)\).
- \( \sigma_j \) = Standard deviation of flows in the \(j^{th}\) season.
- \( t_{i+1} \) = A random deviate normally distributed with zero mean and unit variance.
This model has been used by Nathan Buras in his work with dynamic programming in the field of water resources development (10, 11).
APPENDIX A: DISCUSSION OF PROGRAM

The source program, SYMPROP, is written in Fortran IV language for the IBM 360 computer. It is designed to solve analytical models involving water resource control systems. This entails optimization of multistage systems with one state variable, and any given number of decision variables. SYMPROP actually consists of one program and three subroutine subprograms. The tie arrangement between these subroutines is illustrated in Figure A-1.

The control systems mentioned above require an optimal set of decisions occurring over a designated period of time. Time is therefore divided into increments, each of which is treated as a stage for solution by dynamic programming. Because of the irreversible nature of time, these stages are numbered in a forward manner as shown in Figure A-2. The optimal policy at each stage is determined in a relationship between total system gains and interval profit. The chronological nature of this system has necessitated some modification in the superscripts of the function as shown below.

\[ f_k(x_{v}^{(N-k)} \theta^{(N-k+1)}) = \max_{(N-k+1)} \left\{ P \left( x_{v}^{(N-k)} \theta^{(N-k+1)} \right) + f_{k-1}(x_{v}^{(N-k+1)}) \right\} \]
Fig. A-1. The arrangement between subroutines of the source program.
Fig. A-2. A multiple stage process with one state variable and I decision variables at each stage.
where

\( f_k \) = The total profit for a series of \( k \) remaining stages, dollars.

\( k \) = A counting index beginning with 1 at the last stage, \( N \), and progressing by increments of one to \( N \) at the beginning stage, 1.

\( p_{(n-k+1)} \) = The interval profit for a given stage, dollars.

\( \theta_{(n-k+1)} \) = The independent or decision variables involved at each stage, acre ft./mo.

In general, the dynamic program routine generates a set of grid points for the state variable, \( X_v^{(n-1)} \), at the beginning of each stage. The size and nature of this set is dictated by input parameter cards. For each grid point, the search subroutine is called upon to find the optimal set of decision variables, \( \theta_i^{(n)} \), \( i = 1, 2, \ldots, I \). With this information, the model subroutine is then called upon to calculate the corresponding values of \( X_v^{(n)} \), and the interval profit, \( p^{(n)} \). The dynamic program routine can then solve for the optimal policy, \( f_k \). This routine has been generalized so that it may handle as many grid points of the state variable within as many stages as the programmer wishes. Any number of independent variables may be used.

The search subroutine includes the Hooke and Jeeves pattern search technique. This may be used to maximize an objective function with as many decision variables as desired. The sub-
routine is fed a base point consisting of an arbitrary set of values, one for each decision variable. The Hooke and Jeeves technique employs a perturbation pattern about this base point in search for an optimal set of values.

The value of the profit function is calculated in the model subroutine after each perturbation in the pattern search. This subroutine specifies the objective function connected with a specific model. If the function is subject to a set of constraints, a constraint subroutine may be added to the main program. The search subroutine has been modified to handle this possibility. In addition to calling the model subroutine after each perturbation, the search subroutine also draws the constraint subroutine to check the validity of each step. Success or failure of each evaluation will incur the same routing decisions specified for the model subroutine. In this manner, the search subroutine has the capability of moving along a boundary zone where an optimum point may exist.

The search subroutine has also been modified to accept any number of initial base points desired by the programmer. Before returning control to the dynamic program routine, the search subroutine will select the best result from several trials, each starting from a different base point. This feature is designed to achieve proper convergence in complex problems with local peaks or ridges in hyper-space. The result of each trial
is included in the printed output. This allows the programmer to monitor the success of the search subroutine.

In the following paragraphs, a set of directions has been supplied for prospective users of the SYMPROG program. Modifications have also been suggested for those who wish to use specific subroutines from this program to solve different problems.

DIRECTIONS FOR USING THE SOURCE PROGRAM

The heart of SYMPROG is the dynamic program routine and the search subroutine subprogram. Other model subroutines with different parametric values and constraints may be tied into this center. The recommended order in which the source deck should be arranged is listed as follows.

Job cards
Dynamic program routine
Search subroutine subprogram
Model subroutine subprogram
Constraint subroutine subprogram
Job cards
Input data
Job card
Dynamic Program Routine

All data is read in at the beginning of this routine. The first three values are integer. They are placed in columns 1-5 on separate cards under the format (I5). This input corresponds to the following parameters.

\( NE \) = The number of times perturbation size is reduced before the search subroutine terminates a search pattern.

\( K \) = The number of independent or decision variables that are involved in the solution.

\( M \) = The number of initial base points which will be used in separate trials by the search subroutine.

The following data is floating point. Each value is placed in columns 1-12 on separate cards under the format (E 12.5). This input corresponds to the following parameters.

\( TOM \) = The operating and maintenance costs associated with a given system, dollars/mo.

\( S \) = The total number of stages considered in the dynamic program routine.

\( R \) = The interest rate of money prorated on a monthly basis.

\( D \) = A parameter controlling the number of grid points associated with the state variable \( x_{1t} \).
ALOW = The lowest value considered in the grid network for the state variable, acre ft.

AHIGH = The highest value considered in the grid network for the state variable, acre ft.

BET = The factor by which perturbation size is cut when the search subroutine encounters a disruption in the search pattern.

DEL(I) = The list of initial step sizes used for each decision variable in the perturbation pattern of the search subroutine.
    I = 1, K

BA(I, N) = The list of initial base points used by the search subroutine in separate trial search patterns.
    I = 1, K
    N = 1, M

The SYMPOG program will accept values of
K up to 9
M up to 9
D up to 19

All other input parameters may be assigned any value necessary to accommodate the solution of a problem. If greater values are required for those parameters listed above, modify the dimension statements at locations 3, 4, and 83 such that

DEL(9) is changed to DEL(K)
BA(9, 9) to BA(K, M)
BAH(9, 9) to BAH(K, M)
XV(20) to XV(D+1)
$XV0(20)$ to $XV0(D+1)$
$X(9)$ to $X(K)$
$FB(20)$ to $FB(D+1)$
$FBO(20)$ to $FBO(D+1)$
$DELP(9)$ to $DELP(K)$
$TH(9)$ to $TH(K)$
$BAP(9,9)$ to $BAP(K,1)$
$BF(9)$ to $BF(K)$

where $K,M,$ and $D$ represent the higher values desired for the respective parameters.

The model used in this program requires four decision variables. These variables are labeled as $X1$, $X2$, $X3$, and $X4$ in the format at locations 6-8. If more than four independent variables are used in a given system, this format should be expanded.

At locations 31 and 32 are two call statements. One involves the search subroutine, and the other achieves connection with the model subroutine (labeled CRIT). In location 32, the four decision variables must again be referred to separately as $X(1)$, $X(2)$, $X(3)$, and $X(4)$. If more than four decision variables are used, this statement should be expanded. This change will also affect the number of dummy arguments in the subroutine statement at location 171. When values are calculated in a subroutine and brought back to the calling program,
the arguments used should be initialized. In this case the arguments are X (for the array X(I), I=1,K), PI, XVO(J), and XPO. They are initialized in locations 30.1 - 30.6. Different systems may involve different arguments. If so, they must be defined before engaging the call statement.

Search Subroutine Subprogram

In this subroutine, call statements are used to connect with the model and constraint subroutines at locations 98, 99, 99.1, 109, 110, 111, 121, 125, 126, 133.3, 133.4, 133.5, 135, 140.4, 140.5, 140.6, 154.1, and 154.2. In each case, the first four arguments are related to the four decision variables. These arguments must be expanded in problems calling for more than four independent variables. In addition, subroutine statements at locations 171 and 214 should have their arguments expanded in accordance with this change.

Model Subroutine Subprogram

Additional information required by this subroutine for calculations is supplied through arguments in the call statement. Two values which must be returned to the calling programs (regardless of the model used) are the calculated values of the state variable, \( X^m \), and the interval profit, \( f^m \), for each stage
n. They are required both by the dynamic program routine and the search subroutine in order to function.

Constraint Subroutine Subprogram

The method of testing a proposed perturbation against a series of constraints is illustrated by statements in locations 213 - 232. If the system under study is without constraints, the following modifications should be made.

1. Remove statements at locations 99.1, 111, 133.5, and 140.6.
2. Replace locations 133.5 and 140.6 with the statement: GO TO 191.

Output Data

The results are printed under a two line format for each grid point of the state variable \( x_v^{(n-1)} \).

Line One

\[ B = k \]  The counting index used to denote stage position in the dynamic program routine.

\[ J = j \]  Grid point designation of the state variable \( x_v^{(n-1)} \).

Line Two

\[ XVJ = (x_v^{(n-1)})_j \]  The \( j^{th} \) grid value of a state variable. The
average reservoir volume during stage n-1, acre ft.

\[ X_1 = \theta_{UR}^{(n)} \] Scheduled release of water for urban use during stage n, acre ft./mo.

\[ X_2 = \theta_{IR}^{(n)} \] Scheduled release of water for irrigation during stage n, acre ft./mo.

\[ X_3 = \theta_{ER}^{(n)} \] Scheduled release of water in excess of \( \theta_{UR}^{(n)} \) and \( \theta_{IR}^{(n)} \) during stage n, acre ft./mo.

\[ X_4 = \theta_{TB}^{(n)} \] Water flow from the reservoir which cannot be utilized for hydroelectric power, acre ft./mo.

\[ X_{VOJ} = (X_v^{(n)})_j \] The \( j^{th} \) grid value of a state variable. The average reservoir volume during stage n, acre ft.

\[ FBJ = f_k \] The total profit for a series of k remaining stages in the dynamic program routine, dollars.

Directly above this information are several lines of additional output. The number of lines corresponds to the number of initial base points inserted by the programmer. The results of each line represent the optimal values calculated by the search subroutine from a given base point. The best of several trials is selected for the final output listed below. Each line carries the following information from a given trial.

\[ PI = P^{(n)} \] The interval profit associated with a stage n, dollars.

\[ X(I) = \theta_{1}^{(n)}, i = 1,4 \] The four decision variables, \( \theta_{UR}^{(n)}, \theta_{IR}^{(n)} \),
\( \theta_{\text{ER}}^{(n)} \) and \( \theta_{\text{TB}}^{(n)} \).

If more than four independent variables are involved, their values will be printed below this line.
APPENDIX B. DISCUSSION OF THE HOOKE AND JEEVES PATTERN SEARCH TECHNIQUE

Hooke and Jeeves (12) have devised an approach for staying on the crest of a ridge in hyper-space while searching for an optimum point. Their pattern search technique is based on the conjecture that any set of moves (adjustments of the independent variables) which have been successful during early experiments will be worth trying again. This strategy is successful on straight ridges because the only way an early pattern of moves can succeed is if it lies along the crest. Hence further moves in the same direction will be worthwhile if the ridge is straight.

Although the method starts cautiously with short excursions from the starting point, the steps grow with repeated success. Subsequent failure indicates that shorter steps are in order, and if a change in direction is required the technique will start over again with a new pattern. In the vicinity of the peak, the steps become very small and cannot overlook any new promising direction.

In visualizing what is meant by a pattern, it is useful to think of an arrow, its base at one end and its head at the other. The search begins at an initial base point, $b_i$, which may be chosen arbitrarily. The experimenter then chooses a
step size \( \delta_i \), for each independent variable, \( \theta_i \), \( i=1,2,\ldots,I \). Let \( \delta_i \) be the vector whose \( i \)th component is \( \delta_i \), all the rest being zero. After measuring the criterion at the initial base, one takes an observation at \( b_1 + \delta_1 \). If this new point is better than the base, it is registered as the temporary head \( t_{1,1} \). The double subscript shows that the first pattern is being developed, and that the first variable, \( \theta_1 \), has been perturbed. If \( b_1 + \delta_1 \) is not as good as \( b_1 \) then \( b_1 - \delta_1 \) would be tried. If this new point is better than \( b_1 \) it would be made the temporary head. If not, \( b_1 \) is designated temporary head.

Perturbation of \( \theta_2 \), the next independent variable, is carried out in a similar manner, this time about the temporary head \( t_{1,1} \) instead of the original base, \( b_1 \). In general, the \( i \)th temporary head, \( t_{1,i} \), is obtained from the preceding one, \( t_{1,i-1} \), in the following manner (13).

\[
t_{1,i} = \begin{cases} 
  t_{1,i-1} + \delta_i & \text{if } f(t_{1,i-1} + \delta_i) > f(t_{1,i-1}) \\
  t_{1,i-1} - \delta_i & \text{if } f(t_{1,i-1} - \delta_i) > f(t_{1,i-1}) > f(t_{1,i-1} + \delta_i) \\
  t_{1,i-1} & \text{if } f(t_{1,i-1}) \geq \max(f(t_{1,i-1} + \delta_i), f(t_{1,i-1} - \delta_i))
\end{cases}
\]

This expression covers all values of \( i \) from 1 to \( I \) if the convention is adopted that

\[
t_{1,0} = b_1
\]
When all of the variables have been perturbed, the last temporary head point, \( t_{1,1} \), is designated the second base point, \( b_2 \).

The original base point, \( b_1 \), and the newly determined base point, \( b_2 \), together establish the first pattern. It may be reasoned that if a similar exploration were conducted from \( b_2 \), the results would likely be the same. If so, local excursions may be skipped, and the pattern extended immediately, doubling its length. This establishes a new temporary head, \( t_{2,0} \), for the second pattern based at \( b_2 \). This initial temporary head is given by

\[
t_{2,0} = b_1 + 2(b_2 - b_1) = 2b_2 - b_1
\]

The double subscript, \( 2,0 \), indicates the beginning of the second pattern before any perturbations have occurred about the temporary head.

The search pattern is expanded until none of the temporary heads are any better than the preceding base point. In this case

\[
b_1 = b_{1+1}
\]

The pattern is destroyed. Since this could mean it has reached
a peak or crossed a resolution ridge, new maneuvers are in order. With the termination of one pattern, an attempt must be made to build a new one about the last successful base point, $b_i$. This point is made the initial temporary head, $b_i,0$ for a local exploration. If not, the perturbation steps must be shortened in an attempt to break the resolution ridge that may exist. The search pattern is ended when the step sizes fall below a preselected minimum. At this point it is concluded that a peak has been located, at least as far as can be determined with the finest resolution available.

This discussion has been in connection with the standard Hooke and Jeeves pattern search technique. Since no provision has been made for constrained problems, the computer search subroutine has been modified to allow for this. Discussion of this modification is included in Appendix A.
APPENDIX C. COMPUTER PROGRAM AND RESULTS

Within this section is a compilation of work related to the computer program, and the output from this program. Below, a list of the contents of the following pages has been submitted.

TABLE C-1 (CONTINUED)

JD = J. The number of grid points associated with the state variable, $X^{(n-1)_v}$.

JH = j. This was devised to retain initial values in the dynamic program routine.

JHS = j+1. This was devised to retain initial values in the dynamic program routine.

JZ = j. This was devised to retain initial values in the dynamic program routine.

K = I. The number of independent or decision variables used in the system.

KC = A counter mechanism used in the search subroutine.

M = The total number of initial base points which will be used in the pattern search.

N = m. Subscript designation of the initial base point, $b^{l_1,i_1,m_1}$, introduced into the Hooke and Jeeves pattern search.

NC = A counter mechanism used in the search subroutine.

NE = The number of times perturbation size is reduced before the search subroutine terminates a pattern.

OHB = $\phi^{(n)}_{HB}$. System gain or benefit accrued from hydroelectric power during stage n, dollars/mo.

OHL = $\phi^{(n)}_{HL}$. Loss sustained from power shortage below target output demand for stage n, dollars/mo.
TABLE C-1 (CONTINUED)

\[ OIB = \phi_{IB}^{(n)} \] System benefit accrued from irrigation during stage \( n \), dollars/mo.

\[ OIL = \phi_{IL}^{(n)} \] Loss sustained from irrigation shortage below the target output demand for stage \( n \), dollars/mo.

\[ ORB = \phi_{RB}^{(n)} \] System benefit accrued from water based recreation during stage \( n \), dollars/mo.

\[ OUB = \phi_{UB}^{(n)} \] System benefit accrued from water supply to urban areas during stage \( n \), dollars/mo.

\[ OUL = \phi_{UL}^{(n)} \] Loss sustained from urban supply shortage below the target output demand for stage \( n \), dollars/mo.

\[ PI = P^{(n)} \] The interval profit associated with a stage \( n \), dollars.

\[ PIB = PI \] This was devised to retain initial values in the search subroutine, dollars.

\[ PIV = PI \] This was devised to retain initial values in the search subroutine, dollars.

\[ R = r \] The interest rate of money prorated on a monthly basis.

\[ S = N \] The total number of stages considered in the dynamic program routine.

\[ T = S^{(n)} \] Net economic gain accrued within the system during stage \( n \), dollars.
TABLE C-1 (CONTINUED)

TH(I) = \( t_{i,j} \). The \( i \)th component of a temporary head used to extend the Hook and Jeeves pattern search.

TOM = \( \text{Tom} \). Total operating and maintenance costs incurred during stage \( n \), dollars.

X(I) = \( \theta_{i}^{(n)} \). Value of the \( i \)th decision variable calculated in the search subroutine.

XV(J) = \( \left( x^{(n-1)} \right)_{j} \). The \( j \)th grid value of a state variable. The average reservoir volume during stage \( n-1 \), acre ft.

XVO(J) = \( \left( x^{(n)} \right)_{j} \). The \( j \)th grid value of a state variable. The average reservoir volume during stage \( n \), acre ft.

XVJ = XV(J). A dummy argument, acre ft.

XVOJ = XVO(J). A dummy argument, acre ft.

XVN = XVO(J). This was devised to retain initial values in the dynamic program routine, acre ft.

XTR = \( \left( x_{\text{TR}}^{(n)} \right) \). Average flow rate utilized for production of hydroelectric power during stage \( n \), acre ft./mo.

XUR = \( \theta_{\text{UR}}^{(n)} \). Scheduled release of water for urban use during stage \( n \), acre ft./mo.

XIR = \( \theta_{\text{IR}}^{(n)} \). Scheduled release of water for irrigation during stage \( n \), acre ft./mo.

APPENDIX D. PLOTS SHOWING RESULTS OF A SAMPLE OPTIMAL PATH

In Table C-4, a list of the output from the computer program was printed. This represents the solution of dynamic programming applied to a twelve stage system. As an example, the initial state variable \( x_v^{(0)} = 4.55 \times 10^4 \) acre ft. was chosen arbitrarily, and an optimal path plotted from this table. Figures D-1 through D-6 show the nature of this path as it ranges through a time period of twelve months. The variation of the state variable as well as the decision variables are included in these plots. Because of the nature of the model, most of the variables were subject to constraints. The values of these constraints have been placed in the plots that follow. Doing so illustrates any tendency of the optimal path to move along boundary zones.
Fig. D-1, Example of optimal $\Theta_1^{(n)}$ for a 12 stage system.
Fig. D-2. Example of optimal $\Theta_2^{(n)}$ for a 12 stage system.
Fig. D-3. Example of optimal $\Theta^*_{5}$ for a 12 stage system.

Decision variable, $e_{10^3}$ core ft$/m$. 

$X_1 = 1.5 \times 10^4$

Time Increment, months

Lower limit, $\Theta_5 = 1.0 \times 10^3$
Fig. D-4. Example of optimal $\Theta_{2}^{(n)}$ for a 12 stage system.
Fig. D-5. Example of optimal $X_Y^{(n)}$ for a 12 stage system.
Upper limit, \( X_{TOT}^{(n)} = 1.3 \times 10^4 \)

Fig. D-6. Example of optimal \( X_{TOT}^{(n)} \) for a 12 stage system.
**NOMENCLATURE**

\[ A = \text{Expected deviation of short term fluctuations. A coefficient of the hydrology generator, acre ft./mo.} \]

\[ B = \text{Expected deviation of long term fluctuations. A coefficient of the hydrology generator, acre ft./mo.} \]

\[ b_{i,m} = \text{The } i^{th} \text{ component of a base point used in the Hooke and Jeeves pattern search.} \]

\[ D = \text{Expected deviation of seasonal fluctuations. A coefficient of the irrigation target output demand, acre ft./mo.} \]

\[ d_o = \text{Mean flow rate required by the irrigation target output demand, acre ft./mo.} \]

\[ e = \text{The efficiency factor for a hydroelectric system.} \]

\[ f_k = \text{The total profit for a series of } k \text{ remaining stages. Dynamic programming analysis, dollars.} \]

\[ f_{k-1} = \text{The total profit for a series of } k-1 \text{ remaining stages, dollars.} \]

\[ I = \text{The number of independent or decision variables used in the system.} \]

\[ i = \text{Subscript designation of a specific decision variable.} \]

\[ j = \text{Grid point designation of the state variable } X^{(n-1)}. \]

\[ J = \text{The number of grid points associated with the state variable, } X^{(n-1)}. \]
$K$ = A conversion factor relating hydroelectric power output to system parameters, k.w. hrs./acre ft.$^2$.

$k$ = A counting index indicating stage position in the dynamic programming analysis.

$l$ = Subscript designation of the number of iterations performed in the Hooke and Jeeves pattern search.

$m$ = Subscript designation of the initial base point $b_{l,i,m}$ introduced into the Hooke and Jeeves pattern search.

$M$ = The total number of initial base points which will be used in the pattern search.

$N$ = The total number of stages considered in the dynamic program routine.

$n$ = A superscript indicating a specific time increment or stage.

$f^{(n)}$ = The interval profit associated with a stage $n$, dollars.

$q_o$ = Mean flow rate used by the hydrology generator, acre ft./mo.

$r$ = The interest rate of money prorated on a monthly basis.

$g^{(n)}$ = Net economic gain accrued within the system during stage $n$, dollars.

$t$ = Time as a continuous variable, months.

$t_{1,i}$ = The $i^{th}$ component of a temporary head used to extend the Hooke and Jeeves pattern search.
\( T_B^{(n)} \) = Total benefit accrued within the system during stage \( n \), dollars.

\( T_P^{(n)} \) = Total penalty or loss contracted within the system during stage \( n \), dollars.

\( T_{om}^{(n)} \) = Total operating and maintenance costs incurred during stage \( n \), dollars.

\( V \) = Present value of net system gain accrued during the period of economic analysis, dollars.

\( X_{h}^{(n)} \) = Average head during stage \( n \), ft.

\( X_{HT}^{(n)} \) = Target demand for hydroelectric power during stage \( n \), k.w. hrs./mo.

\( X_{IT}^{(n)} \) = Irrigation target output demand during stage \( n \), acre ft./mo.

\( X_{UT}^{(n)} \) = Urban target output demand during stage \( n \), acre ft./mo.

\( X_{TR}^{(n)} \) = Average flow rate utilized for production of hydroelectric power during stage \( n \), acre ft./mo.

\( X_{TOT}^{(n)} \) = Total flow rate of water released from the reservoir during stage \( n \), acre ft./mo.

\( X_{po}^{(n)} \) = Output of power plant during stage \( n \), k.w. hrs./mo.

\( X_{RA}^{(n)} \) = Attendance for water based recreation during stage \( n \), visitor-days per acre of reservoir surface per month.

\( X_{RS}^{(n)} \) = Average reservoir surface area during stage \( n \), acres.

\( X_{V}^{(n)} \) = Average reservoir volume during stage \( n \), acre ft.
\( \chi_{v}^{(n-1)} \) = Average reservoir volume during stage n-1, acre ft.

\( \chi_{Q}^{(n)} \) = Flow rate of water into the system during stage n, acre ft./mo.

**GREEK LETTERS**

\( \theta_{k} \) = The factor by which perturbation size is cut when the search subroutine encounters a disruption in the search pattern.

\( \varepsilon_{k} \) = The perturbation size used in the Hooke and Jeeves pattern search.

\( \omega \) = A frequency factor of short term fluctuations in the hydrology generator, cyc./mo.

\( \omega' \) = A frequency factor of long term fluctuations in the hydrology generator, cyc./mo.

\( \omega'' \) = A frequency factor of seasonal fluctuations in the irrigation target output demand, cyc./mo.

\( \Phi_{hgh}^{(n)} \) = System gain or benefit accrued from hydroelectric power during stage n, dollars/mo.

\( \Phi_{iil}^{(n)} \) = Loss sustained from power shortage below target output demand for stage n, dollars/mo.

\( \Phi_{lgh}^{(n)} \) = System benefit accrued from irrigation during stage n, dollars/mo.

\( \Phi_{lli}^{(n)} \) = Loss sustained from irrigation shortage below the target output demand for stage n, dollars/mo.
\[ \phi_{RB}^{(n)} = \text{System benefit accrued from water based recreation during stage } n, \text{ dollars/mo.} \]

\[ \phi_{UB}^{(n)} = \text{System benefit accrued from water supply to urban areas during stage } n, \text{ dollars/mo.} \]

\[ \phi_{UL}^{(n)} = \text{Loss sustained from urban supply shortage below the target output demand for stage } n, \text{ dollars/mo.} \]

\[ \phi_{UB}^{(n)} = \text{Unit benefit from hydroelectric power output, dollars/kw. hr.} \]

\[ \theta_{UR}^{(n)} = \theta_1^{(n)}, \text{ Scheduled release of water for urban use during stage } n, \text{ acre ft./mo.} \]

\[ \theta_{IR}^{(n)} = \theta_2^{(n)}, \text{ Scheduled release of water for irrigation during stage } n, \text{ acre ft./mo.} \]

\[ \theta_{ER}^{(n)} = \theta_3^{(n)}, \text{ Scheduled release of water in excess of } \theta_{UR}^{(n)} \text{ and } \theta_{IR}^{(n)} \text{ during stage } n, \text{ acre ft./mo.} \]

\[ \theta_{Rz}^{(n)} = \theta_4^{(n)}, \text{ Water flow from the reservoir which cannot be utilized for hydroelectric power, acre ft./mo.} \]

MODELING AND OPTIMIZATION OF A WATER RESOURCE CONTROL SYSTEM

by

DAVID LOUIS MEYER

B. S., Kansas State University, 1965

AN ABSTRACT OF A MASTER'S REPORT

submitted in partial fulfillment of the requirements for the degree

MASTER OF SCIENCE

Department of Chemical Engineering

KANSAS STATE UNIVERSITY
Manhattan, Kansas

1969
The purpose of this thesis was to devise an efficient approach to water resource control optimization. A test system has been constructed and solved within an analytical framework.

While constructing a model for the test system, particular attention was devoted to sources of water supply, water demand, and the measures available for meeting these demands. The major elements of water supply are components of surface and ground water flow as well as natural storage. Relevant characteristics are quantity, quality and availability measured with respect to time and location. Data used in the model was drawn from the literature wherever possible. This practice was adopted to insure realistic response behavior. In addition, this data is of a form which subsequently may be determined for the analysis of real systems.

The criteria against which operational policies are judged is their effect on the monetary benefits and consequences accrued by each demand source. Consequently, functions have been derived for each source, relating economic gains or losses as a function of scheduled releases within the system. Each point from a benefit function measures the resource cost of providing equivalent goods and services by the least costly alternative. Each point from a loss function measures the penalty of failure to meet a target output demand.
The objective function developed in the system model consists of four decision variables and one state variable applied at each of \( N \) stages. Solution, consequently, fell quite naturally in the realm of dynamic programming. At each stage in the dynamic program routine, a search was conducted by the computer for an optimal set of values which influenced the control policies for that stage. This was accomplished by the Hooke and Jeeves pattern search technique. The search subroutine was modified somewhat, so that it could handle constrained problems. The solution is printed in table form for a twelve stage problem. With output data in this form, one may select an initial (or final) state variable from a list of grid values, and then trace an optimal path relating control policies against time. The size of the list found in these tables is controlled by input parameter cards. The size, and hence accuracy may be varied to fit the needs of the problem. The system model was developed with the idea that it could be modified or extended to cover different situations. Consequently, the dynamic program routine and the search subroutine were written in as general a manner as possible. They can, if desired, be utilized by completely separate model and constraint subroutines.
