INTRODUCTION

Purpose

Cyclic movements in production and prices of many agricultural products are considered to be an indication of imperfect functioning of the market over given periods of time. These cycles may appear as the result of faulty or unsound forecasting of future prices by producers and as a result of factors affecting these prices. Forecasting cattle production and prices is difficult because it is affected by unpredictable elements such as weather conditions, size of corn crops, and fluctuations in general business conditions. Any factor which affects the demand or supply of a product will indirectly influence price, and hence, the production of that commodity under a relatively free economy.

The general aim of this thesis was (1) to compile and correlate data relating to the cattle production cycle, to isolate the causes and effects of the cycle, and to study the inter-relationship of production and price cycles influenced by demand and supply and reflected in price; and (2) to see whether the production cycle or factors relating to it could be used in predicting future trends in the beef cattle industry which would be of value to livestock producers in formulating their production programs.

Scope

An analysis of events taking place during the various phases of the production cycles was used in determining the factors related to the cycle. Included in the scope of the study were trends in cattle numbers and beef production, numbers of cattle per capita of human population, comparison of the cycles as to length, amplitude, and rate of change in numbers; and the inter-relationship of demand, supply, and price.

Beef cattle production has passed through four definite cycles since 1890. Whenever possible all four cycles were considered; however, comparable figures applicable to slaughtering and price constituents were often obtainable for only one or two cycles or portions of various phases of the cycles. Results obtained from such data were not always applicable to all the cycles.

Limitations

Considerable material has been written concerning price and production cycles in general, but little work has been done which refers directly to beef cattle cycles. Limitations in analysis resulted from the difficulty in obtaining comparable data in comparisons covering the same periods of time; in the necessity of using some data in analysis which at best were but good estimates of actual happenings; and from the fact that data concerning the subject were limited to one or two cycles which made generalized statements for all cycles impossible.

Many factors affecting price and production such as weather conditions, practices and policies of cattle producers, and changes in consumer demand are not readily measurable. Only those factors for which measurable data were available could be evaluated with a degree of accuracy.

Much of the material on the slaughter of various classes of cattle dates back to The Packers and Stockyards Act of 1921. From that time on the government collected and published information on the classes of livestock slaughtered in federally-inspected plants. As this period covers only one complete cycle, conclusions based upon facts contained therein cannot be applied without reservations to all four cycles.

Methods of Procedure

The fundamental methods followed in the development of this study were deductions from graphical presentations of factors related to the cattle production cycles and comparisons of these factors by means of multiple correlations to determine if their relationships were significant.

Many of the data pertaining to factors which seemed to be related had to be calculated from other basic data before they could be placed on a comparable basis.

Long time trend lines were used as a measure of the overall picture regarding increases and decreases in cattle numbers, beef production, and slaughter.

REVIEW OF LITERATURE

Factors Responsible for the Cyclic Movement
of Cattle Production

Most economists believe that the underlying causes of the beef production and price cycles are inherent in the cattle industry and may be credited to the tendency of producers to respond to present prices. John A. Hopkins, in his statistical study of the prices and production of beef cattle, contends that these cyclical movements of cattle prices cannot be explained by the tendency first to over-produce cattle for a period of eight or nine years and second, to under-produce for a similar period. He maintains that the cattle cycles result from alienable forces outside the industry. His views may be summarized by his following statements:¹

.... Granting that adjusting cattle production requires a long period does not establish the theory that cattle price and production cycles are to be explained by an inherent and self perpetuating tendency on the part of producers to over and under-produce.

The cattle cycles of the past 60 years are apparently due to forces from outside of the cattle industry, but these forces or conditions which have caused the major crises in the cattle industry do not seem to be related to any regularly recurrent phenomena. The prices of cattle are affected, of course by the general activity or depression of

¹John A. Hopkins, Jr., "A Statistical Study of the Prices and Production of Beef Cattle." Iowa Agricultural Experiment Station Research Bulletin No. 101, December, 1926, p. 351, 356.

business, and are therefore influenced by the general business cycles. This will probably account for a minor series of cycles but not for the major cycles which have been 12 to 15 years in length. No phenomena of a regularly recurrent nature and with a periodicity of 12 or 15 years have come to light to explain the major cycles....

.... The most reasonable conclusion seems to be that the short time variations are simply the responses of the market to the various eventualities such as long and short corn crops, drouths, etc., which befall the producer of cattle for short periods, to the fluctuating demand for beef, which depends to a large degree on the prosperity of the country, and to the supply of possible substitutes for beef, such as pork and mutton. The effects of these various forces on the production and price of cattle are often slow to appear and may have unexpected repercussions before they have run their course.

These statements are basically in accordance with ideas of other economists; the difference being that Hopkins concludes them to be short time variations of various forces affecting the production and prices of cattle which are slow to appear. Other economists, namely Shepherd and Thomsen recognize in the delayed reaction of these "short time variations" sufficient causes for changes in demand and supply of beef cattle and for the response of cattle producers to these changes which result in the wave-like pattern of cattle production. Hopkins does not concede these undulating patterns reflected by cattle numbers to be cycles because differences appear in length, amplitude, and duration; others feel that production cycles cannot be absolute or as "regular as clockwork," and allow for elasticity in the use of the word, cycle.

Relationship of Cattle Production to Price

The general level of prices of all commodities varies greatly over a period of time and the causes of these changes are not always known. To remove fluctuations brought about by the changes in the general price level, it is often necessary to deflate the actual value of a commodity by dividing its value by the index number of prices of all commodities to show what the probable movement of prices would have been had the general price level remained constant.

Geoffrey S. Shepherd found the above method feasible in comparing beef cattle numbers with price.² In his study of the relationship of the cattle production cycle to price, Shepherd found that "cyclic movements in the values of beef cattle per head at the farm cause corresponding changes in the numbers of head of beef cattle on farms--not immediately, but after a lag of several years." He also states that the concurrent inverse correlation between slaughter and the price of beef is not close for "(1) prices at the farm are affected by the demand for breeding purposes as well as by the amount of slaughter, and (2) the effects of changes in consumer demand upon beef cattle prices are only partly removed by dividing the value-per-head series through by the index of the general price level."

General business conditions also are closely associated

² Geoffrey S. Shepherd, Agricultural Price Analysis, (Ames, Iowa, c.1941) p. 63.

with the general price level. Demand for beef and income from meat animals are reflected by changes in consumers' incomes. Lynn Robertson and M. Paul Mitchell of Purdue University Agricultural Experiment Station point out that:³

The income from meat animals moves upward or downward as the national income moves up or down. Changes in demand may be reflected either by changes in price for the same supply or by changes in the quantity consumed or by both.

It thus seems that the price is the most important factor in marketing cattle, and that almost any difficulty in production can be overcome if the price is sufficiently high enough to offset the expense.

LONG TIME TRENDS IN CATTLE NUMBERS AND BEEF PRODUCTION

General Trends

For the purpose of analysis, total cattle numbers were subdivided into beef cattle numbers (which included all cattle other than milk cows) and milk cow numbers. These numbers, listed in Table 1 and graphically presented in Fig. 1, show that following the Civil War, the number of all cattle on farms increased each succeeding year from 28.6 million head in 1867 to approximately 60 million head in 1890. A long-time trend line from 1890 to the present time indicates a definite upward tendency in total cattle numbers on farms in spite of short time variations from the normal trend. Using the trend line as a basis, all cattle numbers increased from 55.5 million in 1890 to 72.1 million in 1945, an expansion of 16.6 million.

The same tendency toward rapid increase from 1867 to 1890 occurred in beef cattle numbers, and from 1890 beef cattle numbers fluctuated similar to total cattle numbers. Again using the trend line as a basis, beef cattle numbers from 1890 to 1945 made but a slight gain of approximately 3.9 million head as compared to the 12.7 million head gain of milk cow numbers. This gain in milk cow numbers has been so steady and so consistent that no trend line was required to compute it. Since the increase in milk cow numbers constitutes more than three-fourths the gain in numbers of total cattle, it is clear that the upward trend in all cattle numbers since 1890 is chiefly

Figure 1. Trend of human population and cattle numbers on farms in the United States on January 1, 1867 to 1945.

the result of the constant increase in dairy cattle numbers.

Although beef cattle have made little if any gain in numbers since 1900, beef production has made a rather substantial increase. With the trend line as reference, beef and veal production increased approximately 36 per cent from 1900 to 1944, while a trend line for beef cattle during the same period indicates a slight decrease in beef cattle numbers. (Fig. 2, Table 2) It must be pointed out that dairy cattle as well as beef cattle contribute to the total beef and veal production. A large proportion of calves produced in dairy sections is sold as veal and older dairy stock is sold as beef.⁴

It would seem without further analysis that a discrepancy exists in the trend line of beef cattle numbers in Fig. 2 as compared with that in Fig. 1; however, the trough between 1890 and 1900 in Fig. 1 has the tendency to lower the trend line at the beginning of the period so that a slight increase in numbers is noted for the longer period. The trend line computed from 1900 to 1944 in Fig. 2 with the absence of this trough shows that a decrease in cattle numbers exists for the shorter period.

There were 43.2 million head of beef cattle on farms, January 1, 1900, and that year the beef and veal production was six billion pounds. In 1939 with only 41.4 million beef cattle on farms, eight billion pounds of beef and veal was

1

produced; consequently, it seems that the country is now producing more beef and veal from the same number of cattle. (Table 2) As further evidence that more beef and veal is being produced without an increase in cattle numbers is illustrated graphically in Fig. 2 which shows a definite increase in the average beef production per head on farms from 1900 to 1944.

Several factors contribute to this apparent increase in beef and veal production without a similar change in beef cattle numbers. Calf slaughter increased sharply from 1918 to 1921 and has continued to increase until at the present time, calf slaughter represents more than one-third of the total federally inspected cattle and calf slaughter.⁵ As most of the calves slaughtered outside the corn belt area come from dairy herds, part of the increase in veal production must be credited to dairy cattle. The effect of beef produced from dairy cattle is negligible as older dairy stock set aside for slaughter represents but a small fraction of total slaughter.

Better management and herd practices in the beef cattle industry have reduced losses of both calves and older stock. Edward M. Wentworth and Rudolf A. Clemen state there has been a decided increase in the number of births per thousand cattle in the United States since 1907.⁶ There has been a movement toward the production of mature cattle ready for market

⁵Dowell and Bjorka, op. cit., p. 76

⁶E. M. Wentworth and R. A. Clemen, "Increasing Productivity of American Livestock Herds." Monthly Letter to Animal Husbandmen, (Armour's Livestock Bureau) 8(2):1-4, October, 1927.

at an earlier age than previously. As shown in Table 3 a growing proportion of beef cows has been retained in cattle herds. This same tendency also was observed from 1920 to 1925 on data covering 29 states compiled by Wentworth and Clemen.⁷

This policy of increasing the percentage of cows and heifers held in herds makes it possible to produce and market a larger number of beef animals each year. At the present time, a given number of beef cattle with a larger proportionate share of cows and heifers will produce more beef annually than the same number of beef cattle (with a smaller ratio of cows and heifers) produced when a larger percentage of steers were kept to an older age.

Long Time Relationship of Cattle Numbers to Human Population

Table 1 and Fig. 3 illustrate the ratio that has existed between cattle numbers and human population from shortly after the Civil War to the present time. In 1867 all cattle numbered 76.6 cattle for one hundred of human population and increased to 95.2 cattle in 1890, the first peak in cattle numbers. Since then, human population has increased much more rapidly than cattle numbers as confirmed by the fact that at the last peak of cattle numbers in 1944, there were only 59.6 cattle per hundred of human population, a reduction of 37.4 per cent since 1890. This decrease in the proportion of total cattle to hu-

⁷Wentworth and Clemen, loc. cit., 7(4):3 October, 1927.

Table 3. Changes in numbers of various age and sex groups of beef cattle in the United States (1900 to 1920) ¹

Groups	Estimated Numbers Jan. 1 1900 (Head)	Actual Numbers Jan. 1 1920 (Head)	Relation to Total		Increase or Decrease Per Cent
			Per Cent	Per Cent	
Calves under 1 year old	8,453,000	8,809,000	22.70	24.55	4.21
Heifers 1 year old and under 2	3,468,000	4,035,000	9.31	11.24	16.35
Cows 2 years old and over	10,821,000	12,730,000	29.07	55.47	17.65

Steers 1 year old and under 2	6,448,000	4,728,000	17.32	13.18	- 26.67
Steers 2 years old and over	7,412,000	4,847,000	19.91	13.51	- 34.61
Total beef cattle	37,231,000	35,884,000	100.00	100.00	- 3.62

¹ 1921 Yearbook of Agriculture, p. 317

Figure 3. Number of cattle in the United States per one hundred human population from 1867 to 1945.

man population can be attributed largely to changes in beef cattle numbers. Beef cattle numbers decreased from 71.4 per hundred human population in 1890 to 39.6 in 1944, a reduction of 44.5 per cent as compared to the reduction of 37.4 per cent in all cattle.

In contrast with beef cattle the proportion of milk cows to human population has remained remarkably constant from 1867 to the present. Note the almost horizontal line in Fig. 3. The number of milk cows per one hundred of human population was 22.1 in 1867 and that ratio has changed little with population growth. The largest ratio was 24.3 in 1871 and 1872 and the lowest was 18.4 in 1928 and 1929. By 1944, the ratio had risen to 20 milk cows for one hundred of population. While human population increased 275 per cent from 1867 to 1945, milk cows increased 236 per cent to maintain a rather stable relationship between human population and milk cow numbers.

CATTLE PRODUCTION CYCLES

Definition of a Cattle Production Cycle

For this study, the definition of production and price cycles as given by Frederick Lundy Thomsen, formerly Professor of Agricultural Economics, University of Missouri, was adopted. Thomsen defines production and price cycles as "...changes in production and price which occur over a number of years with more or less regular periodicity, and which are self-energized or in which one part of the movement follows or is caused by another part. This regularity, plus the self-energizing feature of the cycle, makes it to a certain extent predistable."⁸

The periodic fluctuations in beef cattle numbers will be referred to as cycles as they conform to the qualifications present in Thomsen's definition of a production cycle. The wave-like patterns extend over an interval of years, are comparable in length, are similar in amplitude, and are reciprocal in factors involved in the processes of expansion and liquidation of numbers.

Each cycle is self-activating in that one part of the movement is a continuation of or is caused by the preceding part. For example, when the profits of the cattle industry are sufficient to enable producers to realize a good margin on their

⁸Frederick Lundy Thomsen, Agricultural Prices (New York, c.1936) p. 203.

investment and to induce competitors to enter the field, a program of expansion begins which continues even after the profits have diminished and a state of over-production exists. Liquidation is likewise subjected to a sustained movement until the point of unprofitableness is passed and price has risen to meet the condition of scarcity and demand.

There are characteristics in each phase of the beef cattle cycle which make that phase or portions of it predictable to an extent. In the expansion phase of the cycle and just before the liquidation phase begins, there are times when marketings are increased because breeding stock is being reduced. A rather accurate estimate of the degree of liquidation can be obtained by observing the numbers of cows and heifers going to market. When the trough of beef cattle numbers has been reached and prices tend to be favorable, allowance must be made for the biological factor involved in enlarging a herd, and it becomes obvious that at that stage, three to five years must pass before a substantial increase in slaughtering is observed.

At best the beef cattle cycle can only approximate regularity for the actual contraction and expansion phases of production are influenced by external factors; namely, weather conditions, the size of the corn crop, range and pasture conditions, general business conditions, and the general price level. These factors not readily predictable have a marked effect on the cycle as a whole. It is the opinion of John A. Hopkins, Jr. that the major cattle cycles of the past 60 years

are due to forces outside the industry--forces which do not seem to be related to any orderly repeating occurrence.⁹ However, it is the belief of others that the fluctuations caused by the unpredictable factors serve only to affect the length or emphasize the degree of cyclical variations and that there still remains a truly cyclical pattern of cattle production.¹⁰ The latter interpretation was accepted in this thesis.

Description of Cycle in Beef Cattle Numbers

The fluctuations in beef cattle numbers are primarily responsible for the cyclical variation in cattle numbers. Since 1890 beef cattle have gone through four such complete cycles (figuring from peak to peak in numbers) assuming that the last peak was in 1944 and that cattle numbers now are definitely on the downward phase of the cycle.

Length of Cycle. The cycles vary considerably in length but it is of interest that the increasing phase has been much more consistent in its duration than the decreasing phase. (Table 4)

The factor of regularity in length of the expansion phase renders it more adaptable to prediction than the contraction phase where varying external conditions play a major role in the liquidation of beef cattle. The average of six and one-half years in the increasing portion of the cycle is much more

⁹Hopkins, loc. cit., p. 351.

¹⁰Thomsen, op. cit., p. 360.

Table 4. Length of beef cattle cycle.

Period	Years of Increase Per Cycle	Years of Decrease Per Cycle	Length of Cycle in Years	Per cent of Change in Beef Cattle Numbers	
				Period of Increase	Period of Decrease
1890-1896:	8	6	14	+ 35.7	- 26.7
1896-1904:	8	8	14	+ 35.7	- 30.0
1904-1912:	6	10	16	+ 27.9	- 37.5
1912-1918:	6	4	10	+ 31.0	- 15.0

1928-1934:	6	7	13½	+ 32.6	- 27.3
1934-1939:	6	7	13½	+ 32.6	- 27.3
1939-1944:	6	7	13½	+ 32.6	- 27.3
Average	6½	7	13½	+ 32.6	- 27.3

△ Period of increase and decline calculated from trend line.

reliable than the average of seven years in the declining portion where the variation has been as long as ten years and as short as four years in individual cycles. The great variation in the contraction phase of the cycle has affected the length of the four production cycles as a whole, which has varied considerably with ten years as the minimum length and 16 as the maximum or an average of $15\frac{1}{2}$ years.

The shortest cycle was that from 1934 to 1944 and the longest cycle was that from 1918 to 1934. Some of this variation in length can be attributed to external factors. The severe drouth of 1934 actually brought to a close a normal period of expansion, which was underway, by forcing producers to liquidate a large percentage of their herds and thus start cattle numbers downward. This condition tended, perhaps, to shorten the sixteen year cycle which might have been longer under normal conditions.

On the other hand, the drouth of 1934 and another in 1936 had an accelerating effect on the contraction phase of the 1934 to 1944 cycle. Under the Agricultural Adjustment Act, the government in 1934 and 1935 purchased thousands of head of drouth-stricken cattle. This action had the effect of causing a sharp rise both in cattle price and cattle values and eliminated the cause for the long period of liquidation which usually follows the peak in numbers. Furthermore, the Agricultural Adjustment Act by placing a bonus on the utilisation of grass and pasture land created a great quantity of cheap feed for cattle, particularly in the Corn Belt region. This also helped to decrease

the length of the declining phase of the 1934 to 1944 cycle which might have been of longer duration.

Amplitude of Cycle. Using the long time trend line for beef cattle numbers as a base, it was possible to calculate the per cent of change from this line for the peak and low years. The expansion phases of the four cycles (Table 4) show a much higher degree in regularity of change than does the liquidation phases.

The range of variation in the expansion period was from 35.7 per cent to 27.9 per cent, a difference of only 7.8 per cent. There appears to be a limit to the increase in cattle numbers taking place during the expansion phase. The average increase as calculated from the trend line is around 33 per cent and this increase or growth probably reaches the maximum capacity possible in each cycle for a given number of cattle on farms.

An increase of 33 per cent is a conservative estimate as the period from 1928 to 1934 which was a period of expansion was brought to a sudden close by the drouth of 1934; consequently, the low percentage increase in this period would have a tendency to lower the average for all four cycles. This rather consistent increase in numbers during the expansion phases of the cycles can undoubtedly be attributed to the profitableness of cattle raising during this period which causes producers to expand production to the maximum capabilities of their herds and feed supply in periods of expansion.

In the contraction phases of the cycles the degree of regularity was much less consistent. This lack of consistency can be attributed to the greater variations in length of this phase of the cycle and to the fact that liquidation of a herd can be brought about much more rapidly than the expansion of a herd. Again it is observed that the expansion phase, by its regularity of length and consistency in amplitude, lends itself more readily to predictions or forecasts than the contraction phase of the cycle.

Annual Rate of Change
in Beef Cattle Numbers

To ascertain the degree of regularity in the rate of liquidation and in the rate of expansion of livestock for the four cycles studied, the difference in cattle numbers from a peak to a low period for each liquidation phase, and the difference in cattle numbers from a low to a peak period for each expansion phase was determined; each difference representing 100 per cent for its particular phase. The yearly variations for each phase were then calculated as a per cent of the total difference previously computed for that phase. These percentage changes from year to year, along with the number of cattle on farms and the purchasing power cycle, are presented graphically in Fig. 4. (Table 5)

Expansion Phase of Cycle. There was no definite regularity in the yearly variations of either the expansion or liquidation phases. In the expansion phase three to six years elapsed before the maximum yearly increase in any one phase was

reached. It is interesting to note, too, that the maximum percentage change in all four expansion phases of the cycles ranged between 22 and 28 per cent, so that the limit to expansion in any one year was about 25 per cent of the total change in numbers or approximately 3.5 million head.

Liquidation Phase of Cycle. The liquidation phase of each cycle showed even less regularity in yearly percentage changes than did the expansion phase. Unlike the expansion phase, there is no biological factor limiting the extent of the change. Three to five years may be required for building up a herd which can be liquidated almost immediately. Liquidation is subject more to existing conditions at any particular time; expansion is a result of a decision based upon a forecast of future events and once the decision is made, little can be done to further increase the rate of expansion.

Slaughter as an Indication of Position in Cycle

The percentage of classes of cattle slaughtered in the United States, illustrated graphically in Fig. 5 (Table 6) gives an indication of the predominance of certain classes of cattle slaughtered during the various phases of the production cycle.

During the contraction phase of the cycle the percentage of cows and heifers slaughtered exceeded steers slaughtered for the greater part of the period. From 1920 to 1922, when liquidation progressed at a slow rate, cow and heifer slaughter was less than steer slaughter. However, the remaining six years of

² Data calculated.

the liquidation phase from 1922 to 1928 were characterized by an excess of cows and heifers slaughtered over steers slaughtered. On the other hand, for the entire liquidation phase of 1934 to 1938, when cattle raising was unprofitable and producers were aware of the situation, cows and heifers slaughtered exceeded steers slaughtered.

During the expansion phase as production started upward, the number of the stock slaughtered was reduced and a greater number of steers were slaughtered. (Fig. 6, Table 6) Two to three years before the peak in numbers was reached, the slaughter of breeding stock increased as cattle raising became less and less profitable and steer slaughter started to decrease.

While the percentage of the various classes slaughtered gives an indication of the phase of the cattle production cycle, the fact that any data on cow and heifer slaughter include both beef and dairy cattle, makes it impossible to predict, with any degree of certainty just what changes in numbers are due to beef cattle operations and what changes are due to dairy cattle operations. As changes in beef and dairy cattle numbers occur at different times and from different causes, there is no method of discerning from published data whether an increase of cow and heifer slaughter is due to the liquidation of beef cattle numbers, dairy cattle numbers or both. It is possible that a high percentage of total slaughter could be made up of cows and heifers and at the same time beef cattle numbers could be increasing. For example, if during the expansion phase of the beef cattle

Figure 6. Estimate of classes of cattle slaughtered from 1919 to 1944.

production cycle, the normal number of cows and heifers from beef-breeding herds was being sent to market and at the same time, a sizeable number of cows and heifers from dairy herds was being marketed, the combined numbers would show an increase of cow and heifer slaughter which could be misinterpreted as being caused by large scale liquidation of beef breeding herds. As a whole dairy cattle numbers have been steadily increasing since 1890, but marked seasonal variations in numbers, while affecting the trend of slaughter at a given time, would have little, if any, influence upon the trend of dairy cattle numbers over a longer period.

RELATIONSHIP OF PRICE TO THE CATTLE PRODUCTION CYCLE

The Effect of Demand for Beef on Price of Beef

In livestock production as in other branches of industry, the price paid for a commodity depends in part upon the demand for it as expressed by the desire of individuals for that good plus their ability to purchase it. To support this theory, a comparison was made between retail price of beef and national per capita income.

The data used in comparing national per capita income to the retail price of beef covered the years 1913 to 1941. No earlier material was available than 1913 for national per capita income, and the years following 1941 were omitted purposely to avoid the influence of conditions present during the years of World War II with price subsidies on beef. Plotting the curves for both retail price of beef and national per capita income (Fig. 7, Table 7) showed that the two moved in the same direction with the major fluctuations in national per capita income being reflected in similar fluctuations in retail price of beef.

To measure this relationship a correlation study was made, and a correlation coefficient of .849 was obtained. (Fig. 8, Table 8) This correlation coefficient had a probability of less than .01 which means that by chance such a high correlation could occur less than one time out of a hundred.

The fact that the correlation between national per capita income and retail price of beef was high, is not a basis for determining that one is the cause and the other the effect. A statistical analysis merely shows that a relationship exists, but it does not warrant the conclusion that one factor is dependent upon the other.

A correlation was computed for national per capita income and beef steer prices with a resulting correlation coefficient of .6962 and a probability of less than .01. (Fig. 9, Table 9) Both correlations point toward the supposition that national per capita income undoubtedly is one of the major factors affecting the level of cattle prices.

The Effect of the Supply of Beef on Beef Prices

To determine the effect that beef supply had on beef prices, a means of measuring the relationship of supply to the price of beef was required. It was found necessary to compare total beef production as measured by the dressed weight of total slaughter with beef prices.

Cattle numbers on farms were not used as a basis of beef production because the exact percentage and age of the various classes of cattle on farms was not available and it was impossible to determine the phase of the cycle and the degree of liquidation or expansion taking place at a particular time. If these factors are not known, it would be impossible to come to any conclusion because a large number of cattle on farms in a given year

would not necessarily mean large marketings. Marketings might actually be decreasing and the increase in cattle numbers would be reflecting the number of cows and heifers retained for breeding purposes.

Market receipts were not used as a basis of the supply factor as adverse seasonal conditions such as drought and small feed crops could result in a greater number of cattle being sent to market without showing any appreciable change in the quantity of beef produced in normal years.

On the basis that the yearly total beef production would show a more concrete relationship between supply of beef and price of beef because the effects of short-time fluctuations would be minimized, a correlation analysis was made between the weighted average of beef cattle prices and the total yearly beef production.

Table 10 shows the correlation coefficient for several combinations of beef production and beef prices. With no time lag between production and price there appears to be no significant correlation. It may be that any direct correlation was hidden by factors affecting feeding, grazing, and general management activities which may have entered into the production and price data in such a way as to obscure the true relationship between supply and price.

Time lags between production and price were used to see if the price for any one year might not influence in some way the production policies which would determine the extent of future

Table 10. Correlation coefficients on beef production and beef prices.

Lag Between Price and Production	Correlation Coefficient	Probability ¹

4 year lag.	- .0999	N. S.

¹ A probability of 10 per cent or more is non-significant.

beef supplies. Time lags as great as ten years between production and price were used, but the only significant correlation obtained was that with a two year lag. This correlation was negative--that is, a high price for beef this year would mean a low production of beef two years hence and vice versa. The probability was slightly greater than .04 indicating that this negative correlation could not be discounted as a chance occurrence. However, the large concentration around the regression line between \$5.50 and \$6.50 in Fig. 10 (Table 11) implies that unmeasurable and unpredictable factors may have caused this close correlation.

A negative correlation for a two year lag between production and price can be explained logically in that a high price results in large profits which stimulate production activities and decrease total slaughter. A low price results in unfavorable profits which, if they persist, lead to increased marketing. A time lag of two years for the majority of producers to react to a present situation seems reasonable. The fact that a lag of three years is also negative and has a correlation coefficient of .3327 with a probability of .07 is some indication that these negative correlation coefficients are significant.

The Effect of Purchasing Power of Beef on Beef Cattle Numbers

To make a comparison between beef cattle prices and beef cattle numbers, a deflated average of January 1 farm value per head of beef cattle on farms for the period 1890 to 1945 was used.

Table 11. Two year lag in total beef produced with beef-cattle prices.

This deflated value was computed by dividing the January 1 value of beef cattle by the index number of all commodities for January. (Table 12) The purpose of this procedure was to eliminate so far as possible the fluctuations caused by the general price level. The resulting calculations referred to as purchasing power show what the movement of beef cattle prices would have been if the general price level had remained constant.

Purchasing power of beef passes through a cycle similar to that of beef cattle numbers; however, the peak in the purchasing power cycle did not occur until several years after the low point in the production cycle had been reached. (Fig. 11) This condition is apparently the result of the fact that at the trough of the production cycle when purchasing power is starting to rise, farmers and producers begin to hold back breeding stock from the market, which action in itself would reduce marketings and tend to raise purchasing power. (Fig. 11) This situation continues until expansion has been carried to the point at which marketings increase and purchasing power is lowered.

The peak in numbers came three to five years after the high point in purchasing power was indicated. This may have been because the profits were relatively large at the time of the peak in purchasing power which induced producers to continue expanding their herds and encouraged new producers to enter the field. As production expanded and marketings increased, purchasing power declined until a point was reached at which producers reduced operations. With production on farms decreasing, the cattle numbers started downward and as liquidation progressed, purchasing

power tended to rise until that point was reached that again made conditions for expansion favorable.

The above interpretation of the number and purchasing power cycles implies that producers of beef cattle tend to respond more to present purchasing power conditions than to the prospect of future changes in purchasing power, for when purchasing power is high, few producers are contributing to marketings; while when purchasing power is low, marketings are greatest. With present methods of price and production forecasts and "out-look" data available, it is probable that farmers and producers will use more sound economic information in deciding upon their livestock programs.

The Effect of Purchasing Power on Supply

By comparing the number of cattle slaughtered to the purchasing power of beef cattle, it was possible to show the general effect of purchasing power upon the supply of cattle going to market. This relationship is shown graphically in Fig. 12 (Table 13). There is a definite inverse correlation between cattle slaughter and purchasing power.

From the data available, the peaks in total cattle slaughter lagged the peaks in purchasing power three to five years. Eliminating 1941 to 1945 purchasing power figures which reflect the abnormal war time demand, the peaks in purchasing power figures for the remaining high periods came at a time when cattle slaughter (which represents supply) was at its low point. This implies

² Livestock, Meats, and Wool Market Statistics and Related Data 1943, p. 29; 1944, p. 17.

that producers responded to the high prices by continuing to expand their breeding herds resulting in a reduction in marketings. In fact, slaughter was at a relatively low point two to three years before the peak in purchasing power which infers that with a rise in purchasing power, producers entered into an expansion program which was well underway when the peak in the purchasing power cycle was reached.

Although there was no regularity in the yearly percentage increase in numbers in the expansion phases of the cattle cycle, a comparison of the yearly percentage variations with the purchasing power cycle, showed that the peaks of the percentage changes in two out of four cycles coincided with the peaks in the purchasing power cycle. In one of the other two cycles, the peak in percentage change lagged by one year the peak in the purchasing power cycle, and in the other, the peak of percentage change came four years after the corresponding peak in the purchasing power cycle. (Fig. 13, Table 14)

The most logical explanation of this relationship between peaks is that during the first three or four years of the expansion phase of the cattle cycle before either peak is reached, a large proportion of cows and heifers have been retained for breeding purposes and marketings are relatively low. Low marketings and limited production have a tendency to support a high purchasing power. After the third, fourth, or fifth year, when the greatest percentage increase in cattle numbers occurs, (which can be attributed to the calving of cows and heifers retained on farms at the trough periods of the cycle), marketings increase and purchasing power tends to decline.

SUMMARY AND CONCLUSIONS

The purpose of this study was to collect and systematize data relating to the cattle production cycle and to segregate the causes and effects of the cycle so that the influences of demand and supply upon the cycle could be more clearly defined. The objective of the analysis of the cattle production cycle was to determine whether the cycle or factors relating to it could be employed in predictions of value to livestock producers in the beef cattle industry.

The underlying methods followed in the analysis in this study were deductions from graphical presentations of factors affecting the cycle and the comparison of these factors by means of multiple correlations to determine their relationships.

Limitations in analysis resulted from the difficulty in obtaining comparable data in comparisons involving the same periods of time; the necessity of using data in analysis that at best are only good estimates of actual happenings; and the fact that data concerning the subject were limited to only one or two cycles making generalized statements for all cycles impossible.

Although beef cattle made little gain in numbers following 1900, beef production made a rather substantial increase. With a trend line as reference, beef and veal production increased approximately 36 per cent from 1900 to 1944, while during this same period beef cattle numbers decreased slightly. Factors contributing to this increase in production are: (1) increases in calf slaughter

resulting from an increase in dairy cattle numbers; (2) improved management practices reducing losses of both calves and older stock; (3) increase in number of births per thousand cattle; (4) production of mature cattle ready for market at an earlier age than previously thus permitting an increase in the number of cows and heifers held back in herds and making it possible to produce and market a larger number of beef animals each year.

Beef cattle per one hundred human population decreased from 71.4 cattle in 1890 to 39.6 cattle in 1944, a reduction of 44.5 per cent. During this same period milk cow numbers kept pace with increases in human population maintaining a rather constant ratio of around 20 cows for every 100 of human population.

The lengths and amplitudes of the expansion phases in the cycles studied were much more regular than those of the contraction phases. For this reason the expansion phases were more adaptable to predictions. There was no definite regularity in the yearly percentage changes in cattle numbers in either the expansion or liquidation phases of the four cycles studied.

Although the percentage of the various classes of cattle slaughtered serves as an indication of the phase of the cattle production cycle, the fact that data on cow and heifer slaughter include both beef and dairy cattle, makes it impossible to predict with any degree of accuracy what changes in numbers are due to beef cattle operations and what changes are due to dairy cattle operations.

Since cattle slaughter usually progresses at a high rate after the peak in numbers has been reached, if the monthly com-

position of farm herds were known, a reasonable estimate of production activity could be made. Such information could be used advantageously by cattle producers interested in knowing the seasons of the year when different classes of cattle are being sent to market and in checking estimates of livestock production.

Retail price of beef and national per capita income were found to have a high correlation coefficient of .849 with a probability of less than one per cent. An equally high correlation coefficient (.8015) with a probability of less than one per cent was obtained for national per capita income and beef steer prices. Both correlations point toward the supposition that national per capita income is one of the major factors affecting the level of cattle prices. An estimate of the trend in future prices could be obtained by observing the trend of national per capita income.

With no time lag between yearly slaughter (production) and average yearly beef prices, there appears to be no significant correlation. A significant negative correlation exists for a two-year lag between production and price accountable by the fact that a high price results in large profits which stimulates production activities and decreases slaughter by the holding back of breeding stock. A low price results in unfavorable profits, which, if they persist, lead to increased marketings.

Peaks in purchasing power figures came at a time when cattle slaughter (supply) was at its low point. Producers respond to a high purchasing power by expanding their breeding herds. This action results in a temporary reduction of marketings.

Purchasing power of beef cattle passes through cycles similar

to those of beef cattle numbers. The peaks in the purchasing power cycles did not occur until several years after the low points in the production cycles had been reached. This condition is apparently the reaction of producers to profits.

Producers tend to respond to present purchasing power by expanding or limiting their production policies accordingly; i.e. when purchasing power is high, marketings are low because breeding activities are in full-swing; and when the purchasing power is low, marketings are high, because liquidation is taking place.

Useful data may be obtained in following the movements of the beef cattle production cycle. Changes in the composition of total cattle numbers and yearly cattle slaughter are reported by the various state and federal agricultural agencies. Changes in the classes of cattle slaughtered under federal inspection, which gives an indication of breeding activities, are published by the United States Department of Agriculture. Federal publications report national per capita income which can serve to indicate the future level of cattle prices. Cattle producers can plan more intelligently their livestock programs with these types of information.

ACKNOWLEDGMENTS

Acknowledgment is made to Professor C. Peairs Wilson, for his assistance in all phases of the preparation of this thesis, and to Dr. W. E. Grimes for his constructive criticisms and suggestions.
