## I. INTRODUCTION

### 1.1 History and Purpose of the EHSI Development System

Ever since the Wright brothers made their historic first flight, man has been trying to make flying an easier and safer task. Advances in aeronautical engineering continue to make better aircraft that are easier to fly. But, today, more advancements are being made in the cockpit area. A multitude of analog and digital signals are presented in the cockpit of any aircraft. For many years, all the pilot saw of the signals was an analog meter or a lamp. Recently, though, the age of electronics has made possible methods of displaying flight data on cathode-ray tube (CRT) screens. These displays can greatly reduce pilot workload, thus increasing the safety of flying.

An electronic horizontal situation indicator (EHSI) is a system that displays flight-related data on a cockpit display screen. EHSI's have been developed for military aircraft and commercial airlines, and they have proven to be very useful to the pilots.

Because of the expense of the systems, the general aviation community has not been offered a practical EHSI. With the recent advances in microprocessor technology and the decrease of costs associated with electronics, the possibility of building an affordable EHSI for the general aviation community is being explored.

S. A. Dyer [1] has proposed that an EHSI be developed for general-aviation at a reasonable cost. The EHSI would consist of one or two flight-capable high-resolution screens, a command keyboard, and the necessary electronics and software to display the flight data in useful forms. Display pages showing inflight, navigation, and instrument landing data are proposed. The display pages developed concurrently with this report will be discussed in Chapter 7.

An EHSI Development System is being built at Kansas State University (KSU) to look into the possibilities of producing an EHSI in the eight-to twelve-thousand dollar range. The targeted consumer is the general-aviation community.

## **1.2 Elements of the EHSI Development System**

The basic tasks of the EHSI system include: (1) sampling the analog flight signals, (2) assimilating information to be displayed, and finally, (3) sending the information in a suitable graphical form to the display device. It would also be convenient to include a keypad so that the pilot can interact with the system. Fig. 1 shows a block diagram of the EHSI development system at KSU. An interface driven by a Motorola 68000 based board has been designed and built by J. Lagerberg [2]. This interface, known as the Data Acquisition and Communications Interface

(DACI), controls communication within the system. It also digitizes flight data for use by the rest of the system. The interface detects key presses of the command keyboard on an interrupt basis, and also sends graphics commands to the Hewlett-Packard 1345A vector graphics display. The 1345A is a \$4,000 dollar unit with high resolution and is specified for operation at pressure altitudes up to 15,000 feet. The "Vector Graphics Memory" (VGM) option of the HP-1345A eliminates the need for constant refresh of the screen from the DACI. In other words, the 1345A display is refreshed from commands in the VGM. If the display needs to be changed, the DACI can change parts of the memory, thus altering the display. The flight data being digitized is coming from an ATC-610 Flight Simulator. The ATC-610 provides analog information similar to that available during flight in an airplane. Therefore, the possibility exists of developing near "real-life" situations in the laboratory for the EHSI Development System.

The host computer, a Zenith-158 personal computer, acts as the central processing unit for the EHSI system. The Z-158 does all of the display generation and calculation work for the system. The Z-158 is connected to the DACI via the parallel printer port. Communication has been established between the DACI and the Z-158 in an interrupt environment supported by a handshaking protocol. The routines to accomplish the interface are written in 8088 assembly-

language. Assembly-language is used for maximum speed, but an intermediate-level language, C, is used for the display generation routines. Therefore, interfacing the assembly-language routines with the C functions has also been accomplished.

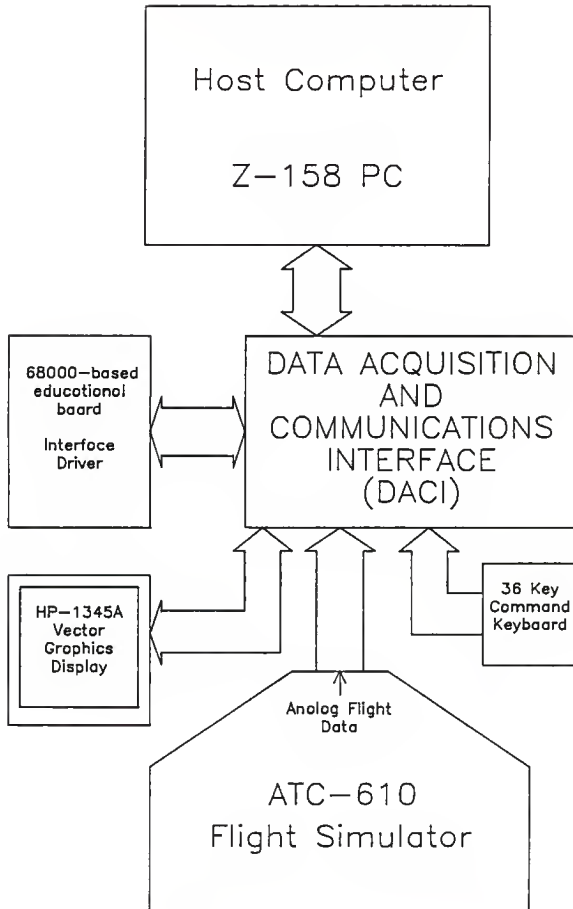

Figure 1. Block diagram of EHSI Development System.

### 1.3 Research Goals and Purpose of This Report

The research covered in this thesis was directed toward the development of the required low-level software to create a suitable operating environment for the Z-158. The goals of the research are:

1. To develop algorithms and implement them in assembly language routines to establish communications between the Z-158 and DACI. The routines must be reliable, easy to access, and fast enough to operate the EHSI in near real-time.
2. To interface the Z-158 with commands written for the DACI by Lagerberg [2].
3. To interface the communications routines with the C functions.
4. To provide reliable and easy to use guidelines for using the communications routines.
5. To analyze samples of data taken from the flight simulator and design digital filters to provide lowpass filtering and differentiation of the analog signals.
6. To provide adequate maintenance information and recommendations to future project members.

## II. SPECIFICATIONS

### 2.1 Communications are carried out through the parallel port

The Z-158 parallel port is a 25-line port that is internally divided into three different addressable ports. One address is for an 8-line I/O databus. Another is for input control lines, and the last is for output control lines. One of the lines can be used to trigger hardware interrupts. The lines used for the Z-158 -to- DACI interface are shown in Fig. 2. Actual hardware connections can be found in Fig. 10.

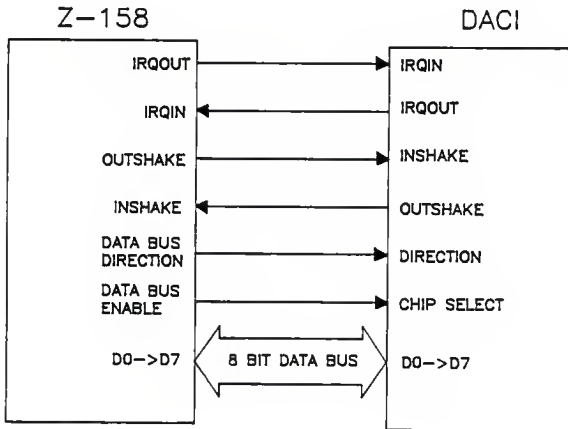

Figure 2. Control and Data lines for the Z-158 -to- DACI interface.

The Z-158 and DACI each have an IRQOUT, IRQIN, OUTSHAKE, and INSHAKE line.

IRQOUT is the line used to initiate an interrupt. This line is connected to the receiving end's IRQIN line. The Z-158 uses its IRQOUT line to interrupt the DACI, and the DACI uses its IRQOUT line to interrupt the Z-158.

The IRQIN lines of the Z-158 and DACI are latched by hardware so that interrupts will not be missed. The Z-158 IRQIN line is connected internally to its 8259A programmable interrupt controller. The DACI IRQIN line is latched to a 6821 PIA. Additional information on the interrupt hardware design of the DACI is available in [2].

All external hardware interrupts are tied to the 8259A within the Z-158. The controller prioritizes interrupts and tells the 8088 central processing unit (CPU) within the Z-158 what interrupt should be serviced next. The 8259A can be programmed to ignore certain interrupts and give higher priority to others. A discussion of how the 8259A is programmed is presented in Sec. 3.5.

DATA BUS ENABLE and DATA BUS DIRECTION are two lines that the Z-158 uses to control the data bus buffer (74LS245) found on the DACI. Before attempting a read or a write to the DACI, the Z-158 must make sure the data bus is appropriately set up. When the data bus is not in use, the bus is kept in the high-impedance state.

The data bus has 8 lines and is bidirectional. A

modification was made to the Z-158 parallel port so that the data bus could be read. The modification is shown and explained in Appendix C.

## 2.2 Communications Between the Z-158 and DACI

### DACI interrupting the Z-158

The DACI interrupts the Z-158 on the occurrence of one of several physical events. The DACI pulses the IRQOUT line after placing the appropriate interrupt vector on the data bus. The Z-158 must then suspend its current process and initiate an interrupt service routine. The Z-158 retrieves the interrupt vector from the data bus and then pulses the OUTSHAKE line. The interrupt service routine of the Z-158 concludes and the suspended process continues. The DACI continues after seeing the acknowledge pulse on its INSHAKE line. The timing diagram in Fig. 3 shows the states of the pertinent lines.

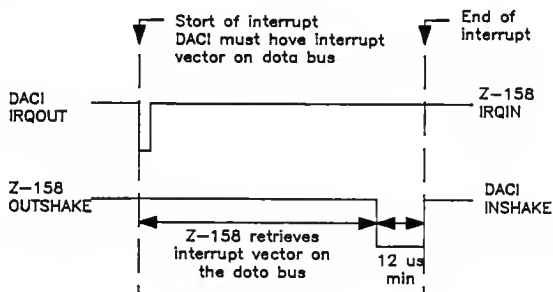

Figure 3. Timing diagram of DACI interrupting the Z-158.

The physical events that cause the DACI to interrupt the Z-158 are:

<u>event</u>	<u>interrupt vector sent</u>
System switch turned on	65H
System switch turned off	66H
System clock updated	60H
A key has been pressed	01H-->23H*

\* interrupt vector is the number of the key pressed. See Fig. 30.

### **Z-158 interrupting the DACI**

The Z-158 interrupts the DACI by pulsing its IRQOUT line after placing an interrupt command vector on the data bus. The four commands and their respective command vectors are given below:

<u>COMMAND NUMBER</u>	<u>FUNCTION</u>
01H:	The Z-158 requests that the flight data package be sent. The data package contains current digitized values of the flight simulator signals, and the system clock.
02H:	The Z-158 wants to send screen commands to the HP-1345A. The words are transferred until the top byte of a screen command contains FFH.
03H:	The Z-158 requests that a certain area of HP-1345A vector memory commands be sent back to the Z-158.
04H:	The Z-158 tells the DACI to toggle the current state of the alarm.

Each command will now be explained in detail.

### Command 01H:

The Z-158 places 01H on the data bus and pulses its IRQOUT line. The DACI will acknowledge by pulsing its OUTSHAKE line. To set up for the transfer of the data package, the DACI places the number of entries of the data package on the data bus and pulses its OUTSHAKE line. The Z-158 reads the number and acknowledges with a pulse on its OUTSHAKE line. The transfer of the data package will then occur within a handshaking environment. After the final entry is received and acknowledged, the Z-158 and DACI return to their interrupted processes.

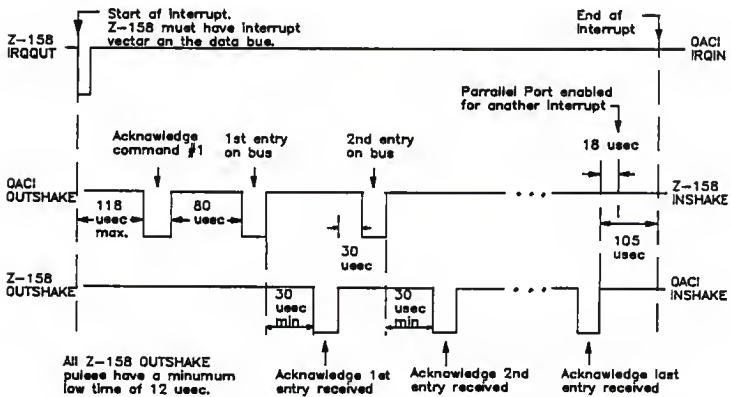

Figure 4. Interface Command 1 timing diagram.

### Command 02H:

The Z-158 places 02H on the data bus and pulses its IRQOUT line. The DACI acknowledges on its OUTSHAKE line,

and the transfer of screen words is ready to begin. Each word is sent as two bytes, first the most-significant byte (MSB) and then the least-significant byte (LSB). The Z-158 places the MSB on the data bus and strobes the DACI. After the DACI reads the byte and acknowledges on its OUTSHAKE line, the Z-158 places the LSB on the data bus and strobes the DACI. The screen words are sent in this fashion until the MSB of a screen word is FFH. This signals the end of the transfer, and the Z-158 and the DACI return to their interrupted processes.

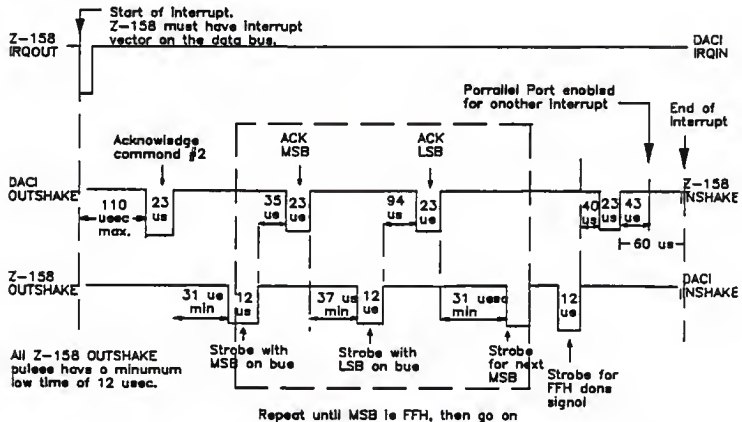

Figure 5. Interface Command 2 timing diagram.

#### Command 03H:

The Z-158 places 03H on the data bus and pulses its IRQOUT line. The DACI acknowledges on its OUTSHAKE line. Using the same handshaking protocol as used in the previous

2 commands, the Z-158 sends the starting address and ending address of the screen memory desired. The DACI then proceeds to transfer the requested screen words to the Z-158. After the last word is sent, the DACI and Z-158 return to their interrupted processes.

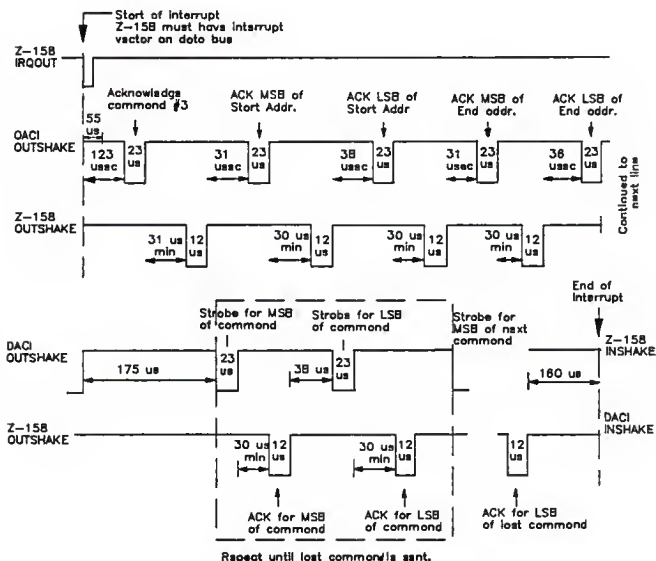

Figure 6. Interface Command 3 timing diagram.

**Command 04H:**

The Z-158 places 04H on the data bus and pulses its IRQOUT line. The DACI will acknowledge the interrupt on its

OUTSHAKE line. The DACI will proceed to toggle the state of the alarm, and the Z-158 and DACI will return to their interrupted processes.

Figure 7. Interface Command 4 timing diagram.

### 2.3 Software Choices

It is worth mentioning the two languages used to implement the algorithms for the interrupt procedures.

Microsoft Macro Assembler (MASM) Version 4.0 by Microsoft, Inc. was used to write the 8088 assembly language routines -- the communication routines which involve interrupt servicing and handshaking. The use of MASM allows good speed of execution and tight control over the object code.

Microsoft C Version 4.0 was used as the high-level language because of its portability, speed compared to other high-level languages, bit manipulation functions, and the extensive libraries that are included with the compiler.

Because the assembler and the compiler were produced by the same company, interfacing the two proved to be a fairly straightforward task.

### III. THE LOW LEVEL SOFTWARE INTERFACE

#### 3.1 Preview of EHSI Operating Environment

Before detailing the communication routines to implement the commands described in Chapter 2, a basic description of how the routines are used is needed. The main program of the system initializes the system, acts on interrupts received from the DACI, and restores the system on shutdown.

The first thing the main program does when invoked is install the interrupt handler and prepare the environment for the EHSI system. The main program will then poll the first element of the "Interrupt Vector Stack", waiting for a non-zero vector. The interrupt handler is the only module that can place vectors on the interrupt vector stack. It places interrupt vectors on the stack when the DACI interrupts the Z-158 with a vector on the data bus. If the main program is slow in servicing the vectors on the stack, the interrupt handler has the capability of stacking the interrupts so that all of them are serviced. As the main program services the interrupts, it rolls the stack down if it detects more than one interrupt on the interrupt vector stack.

When the main program detects an interrupt vector it enters a decision loop to determine what kind of action to take. If a screen needs to be updated, Command 1 will be

called to fetch the current data package. Calculation of the HP-1345A screen code will then take place. Finally, Command 2 will be called to send the screen code through the DACI to the HP 1345A.

The control of the program would then return back to polling the Interrupt Vector Stack. When the shutdown vector is received, a function to restore the environment to its original state is called. The main program would then terminate. See Fig. 8 for an illustration showing system interaction.

Now that the basics of the system have been covered, the low level software can be developed in detail. Sections 3.2 and 3.3 will develop tools for the routines, and Sections 3.4 and 3.5 will show the actual development of the routines.

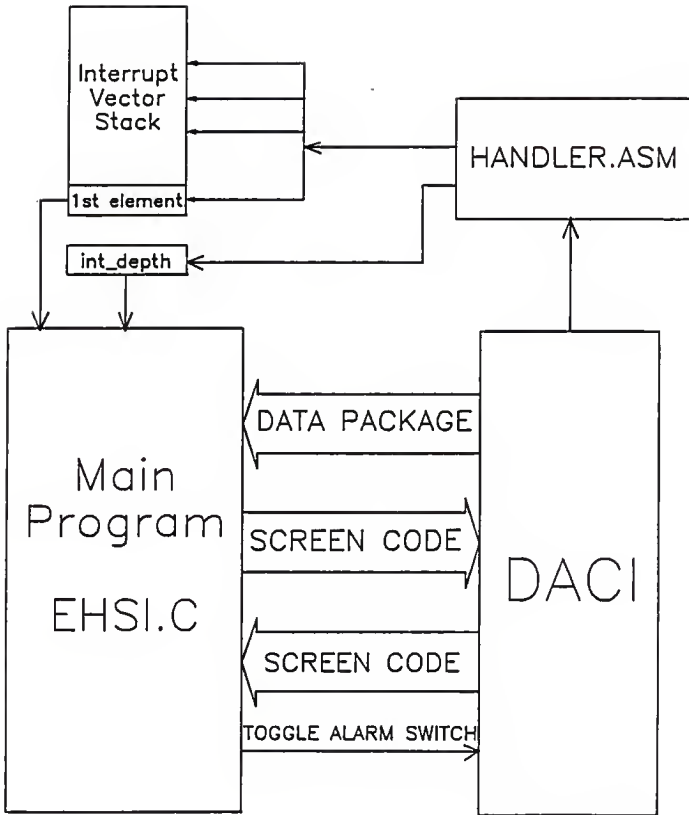

Figure 8. System interaction.

### 3.2 Communicating with the hardware

Before developing the interface functions, it is useful to describe the 8088 assembly language instructions used to communicate through the ports.

To input a byte from a port with address `PORT_ADDRESS`, the following assembly language code is required:

```
mov    dx, PORT_ADDRESS    ; put port number in dx
in     al, dx              ; input byte is now in al
```

The byte read from port `PORT_ADDRESS` is now in the low byte of accumulator `ax`, otherwise known as `al`.

To output a byte, `OUTPUT_BYTE`, through a port with address `PORT_ADDRESS`, the following assembly language code is required:

```
mov    dx, PORT_ADDRESS    ; put port number in dx
mov    al, OUTPUT_BYTE     ; put output byte in al
out    dx, al              ; output al to port dx
```

Three ports control all the lines used in the parallel port interface from the Z-158 to the DACI. Port 378H is the data bus port. Reading this port will read the data bus, and outputting a byte to this port will put that byte on the data bus. Port 379H is the input control line port. Only two lines of Port 379H are used, D4 and D6. D4 is the INSHAKE line, or where the DACI OUTSHAKE's to. D6 is the IRQIN line, or where the DACI IRQOUT's to. Port 37AH is the output control line port. Five of the lines are used. D0 is the Z-158 OUTSHAKE line, D2 is the Z-158 IRQOUT line, D1 controls the direction of the data bus, and D3 controls the

state of the data bus. D4 is set high to enable parallel port interrupts, and low to disable IRQ7.

Port number	line(s)	Z-158 function	DACI connection
378H	D0->D7	Data Bus	Data Bus
379H	D4	INSHAKE	OUTSHAKE
379H	D6	IRQIN	IRQOUT
37AH	D0*	OUTSHAKE	INSHAKE
37AH	D1*	DATA BUS DIRECTION	DIRECTION
37AH	D2	IRQOUT	IRQIN
37AH	D3*	DATA BUS ENABLE	CHIP SELECT
37AH	D4	IRQ7 ENABLE	NONE

\*Actual outputs of these lines are inverted.

Figure 9. Z-158 parallel port line connections.

Figure 10 is a schematic showing the hardware interface in more detail. Notice the three Z-158 ports and their respective names. With the port and line functions now identified, commands can be written to perform specific actions.

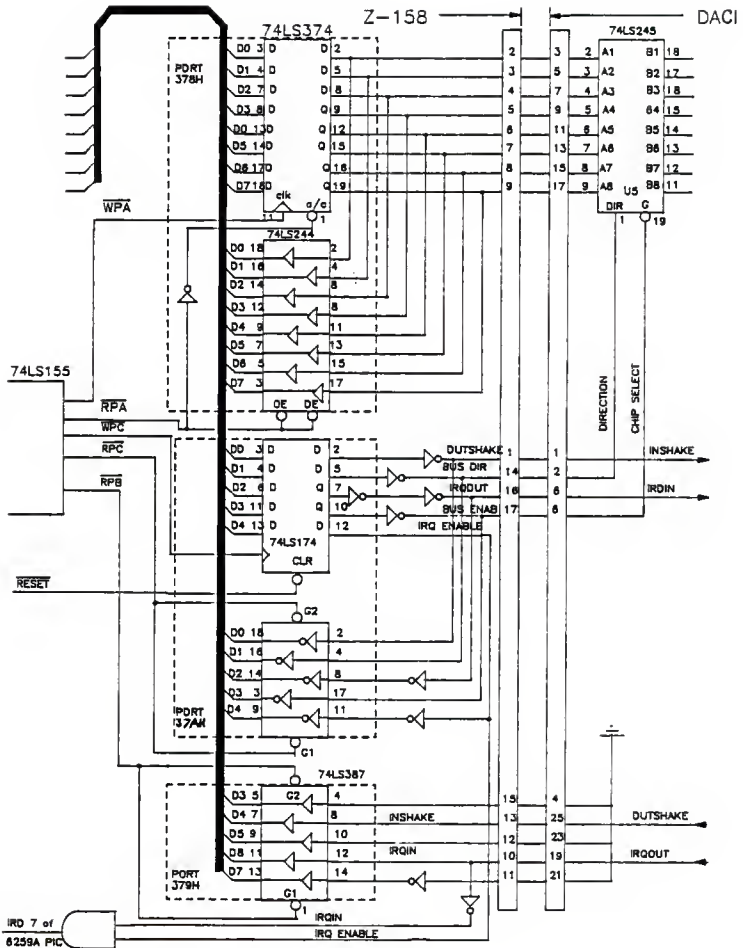

Figure 10. Z-158 -to- DACI Hardware Interface.

The different states of the databus control lines, DATA\_BUS\_ENABLE and DATA\_BUS\_DIRECTION, are summarized in Fig. 11. It should be noted that these lines are inverted in the Z-158.

ACTION	DATA_BUS_DIRECTION PORT 37AH Line D3	DATA_BUS_ENABLE PORT 37AH Line D3
Enable Z-158 to Read	Low	Low
Enable Z-158 to Write	High	Low
Disable Data Bus	Low*	High

\*This would normally be a "Don't Care", but keeping the Z-158 in read mode will help to avoid bus conflicts.

Figure 11. Control states of the data bus control lines.

Line D4 of Port 37AH is the IRQ\_ENABLE line. IRQ\_ENABLE must be high before a high-low transition on the IRQ\_IN line can trigger an interrupt. (See Fig. 10.)

Noting the inverters between Port 37AH's output latch and the 25-pin connector, the states of the port can be found to accomplish different tasks.

To prepare to read the data bus, the following assembly language instructions are issued:

```
mov dx, 037AH
mov al, OFEH
out dx, al
```

Following the data bus preparation is the actual read:

```
mov dx, 0378H
in al, dx
```

After the read, it is good practice to disable the data bus. Since the input byte is in al, it should be stored before performing the following disable bus procedure:

```
mov dx, 037AH
mov al, 0F4H
out dx, al
```

To perform a write to the data bus, a similar procedure of enabling, writing, and disabling the data bus is used:

Enable data bus for a write:

```
mov dx, 037AH
mov al, 0FCH
out dx, al
```

Output the byte OUTPUT\_BYTE:

```
mov dx, 0378H
mov al, OUTPUT_BYTE
out dx, al
```

Disable the data bus:

```
mov dx, 037AH
mov al, 0F4H
out dx, al
```

Other useful sequences of code that are used frequently in handshaking are:

To clear the OUTSHAKE line:

```
mov dx, 037AH           ; load port address
in  al, dx             ; get current state
or  al, 01H           ; set bit D0
out dx, al             ; output the byte
```

Similarly, to set the OUTSHAKE line:

```
mov dx, 037AH           ; load port address
in  al, dx             ; get current state
or  al, 0FEH          ; clear bit D0
out dx, al             ; output the byte
```

To check the level of the INSHAKE line:

```
mov dx, 0379H      ; load port address
in  al, dx        ; get current state
and al, 10H       ; result if 0 if INSHAKE low
                  ; result is 1 if INSHAKE high
```

All of the procedures written so far have been for communications through the parallel printer port, but two ports internal to the Z-158 are important for interrupt handling. Both ports, 20H and 21H, talk directly with the 8259A Programmable Interrupt Controller. The 8259A prioritizes external hardware interrupts, such as the keyboard interrupt and system clock interrupt. The parallel port interrupt is wired directly to the 8259A.

Port 21H gives access to the interrupt mask register. The mask controls which interrupts are serviced or ignored. A low level in the mask corresponds to interrupts being serviced, and a high level means that interrupt is disabled. The table in Fig. 12 shows the interrupts connected to the 8259A and the interrupt mask register bit corresponding to each [4].

<u>DOS</u> <u>Interrupt No.</u>	<u>Function</u>	<u>8259A Interrupt</u> <u>Register Mask Bit</u>	
08H	System Clock	Port 21H	D0
09H	Keyboard Interrupt	Port 21H	D1
0AH	Not used	Port 21H	D2
0BH	Asynch. Port 1	Port 21H	D3
0CH	Asynch. Port 2	Port 21H	D4
0DH	Fixed Disk Controller	Port 21H	D5
0EH	Floppy Disk Controller	Port 21H	D6
0FH	Parallel Port Interrupt	Port 21H	D7

Figure 12. Interrupts vectored through the 8259A.

To enable and disable interrupts vectored through the 8259A, read Port 21H, set or clear the desired mask bits, and send the new mask back to Port 21H. The assembly code can be written as:

```
        mov dx, 21H           ; port number of mask
        in  al, dx           ; read current mask
(set or clear desired bits) ; change the mask
        out dx, al          ; write new mask
```

When interrupts are funnelled through the 8259A, a special command is given at the end of the interrupt service routine to clear the 8259A. Port 20H is the control port used for this purpose. After an interrupt, the following assembly code is used to clear the 8259A:

```
        mov dx, 20H           ; control port number
        mov al, 20H          ; End of Interrupt byte
        out dx, al          ; send EOI to 8259A
```

### 3.3 Interfacing Assembly Language and C

One last subject will now be covered before developing the communication routines between the Z-158 and DACI. The assembly-language routines must be able to read and write to data variables and structures in the main C routine. Writing these routines thus requires some knowledge of the architecture of the 8088's memory.

Memory on the 8088 processor is divided into segments of up to 64K each. Segments are given names to correspond to their contents, and similar segments are grouped together when modules are linked together. Since Microsoft products

were used, Microsoft's segment model was adhered to in the structure of the interface. The segments and their relative locations in memory are shown in Fig. 13.

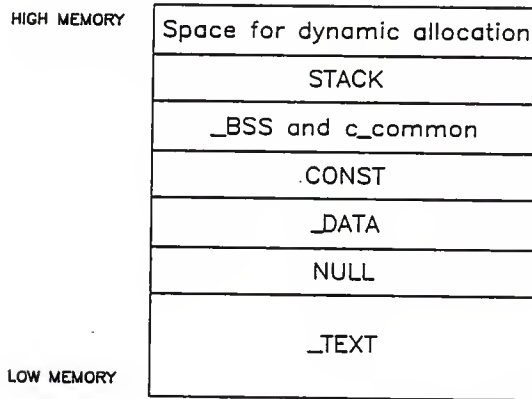

Figure 13. Microsoft segment model.

The contents of the segments shown in Fig. 13 are listed below:

SEGMENT	CONTENTS
STACK	The STACK segment contains the user's stack. This will be a common stack to the C and assembly language routines.
_BSS	The _BSS segment contains all uninitialized static data items.
c_common	The c_common segment contains all global uninitialized data items.

**CONST**                   The **CONST** segment contains all constants that can only be read.

**\_DATA**                   The **\_DATA** segment is the default data segment. All initialized global and static data are put in this segment.

**NULL**                    The **NULL** segment is a special purpose segment that is placed at the bottom of **DGROUP**. The segment contains the compiler copyright notice, and is checked before and after program execution.

**\_TEXT**                   The **\_TEXT** segment contains all the code of the C and assembly language routines.

The above definitions are for small-model programs. A small-model program has two segments that contain all the segments listed above. One segment contains all the code, and the other contains the data. Maximum size for each is 64K, so maximum size of the program cannot exceed 128K. If a problem with size ever becomes a problem, a medium-model program could then be created.

The **\_TEXT** and **\_DATA** segments will be the ones referred to when implementing an assembly-language routine to be called from a C program. The code for the assembly-language routine should be placed in the **\_TEXT** segment, and global data must be placed in the **\_DATA** segment, or else the C and assembly-language will not be able to access the same data. The **\_DATA** segment was defined before to contain all initialized global data items, so data structures and variables needed to be accessed by both the C and assembly-language routines must be initialized. This will ensure the

data of being placed in the `_DATA` segment instead of the `c_common` segment.

A small-model program was mentioned before to contain two segments, but there are seven segments defined in Fig. 13. This is possible because of "groups", which allows the combination of several segments into one. The `_DATA`, `CONST`, `_BSS`, `c_common`, `NULL`, and `STACK` segments are grouped together by the Microsoft C compiler into a group named `DGROUP`. The advantage of groups is that any data in a group can be accessed by the same segment register. Instead of needing two words to access a different piece of data, only the offset in the segment is needed. Thus, access time is nearly halved. After a data transfer of hundreds of words, the time saved can be significant. To summarize what segments are to be used in the assembly-language routines, it can be said that all code shall be in the `_TEXT` segment, and all global data items will be in the `_DATA` segment which is grouped into the `DGROUP`. Listing files of compiles and links will show segment and group names of all data.

It will be necessary to pass arguments from C to assembly-language routines. Arguments are passed on the stack, and the called routine must pop the arguments off the stack. Since words are only pushed and popped from the stack, the number of words pushed for the different data types is needed. Fig. 14 gives the number of words used for the standard data types in C.

data type	Number of words pushed on stack
char, short, int, signed char, signed short, signed int, unsigned char, unsigned short, unsigned int	1 word
long, unsigned long	2 words
float, double	4 words

Figure 14. Argument lengths of C data types.

When C calls an assembly-language routine, the last argument is pushed first and the first argument last. If an argument requires more than one word, the high word is pushed first, followed by the next higher word.

When a C program passes control to an assembly-language routine, certain registers must be preserved or changed before arguments can be grabbed and the routine executed. The BP, SI, and DI registers need to be saved, and the BP register should be set to the current SP register. Any segment values changed in the routine, such as SS, DS, or CS, should also be saved and then restored on exit from the routine. After the entry sequence, the arguments passed can be found on the stack starting at offset bp+4. Each argument must be popped off the stack according to the guidelines of Fig. 14.

With the arguments off the stack, the assembly-language routine then goes about its business. There is one extremely important convention when C and assembly need to use a common global variable or function. The global variable names and function names in the assembly language routine must be prepended by an underscore (\_). If an assembly-language routine is required to access a global data variable named RESULT declared in a C program, the assembly routine must declare \_RESULT as external in the \_DATA segment. The routine can then modify the variable. The same applies toward routine names. If the C program wants to execute an assembly-language routine, the routine name must begin with an underscore. The C function call DO\_IT() will access the assembly language routine named \_DO\_IT, as long as DO\_IT() has been declared external in the calling C program. To summarize, if the assembly-language name does not begin with an underscore, it cannot be accessed in a C program.

As in the calling of C functions from other C programs, arguments are not automatically passed from assembly-language routines when returning to a calling C program. However, a value may be returned to a calling C program by placing the return value in the AX register. This works when returning characters, integers, or shorts, whether signed or unsigned. If a long, float, double, or pointer needs to be returned, see [4] for further information.

After the return value has been put in ax, the assembly-language must restore registers that were preserved on entry to the routine. Si, di, sp, and bp are restored before the return command is given.

An example of an assembly-language/C interface is shown in Fig. 15.

### 3.4 Interrupting the DACI, and data transfer.

The first three sections of this chapter have been devoted to explaining what the communication routines need to accomplish, and the tools available to help accomplish the tasks. In this section, the routines to implement the four commands discussed in Sec. 2.2 are developed.

Five routines have been written to accomplish relatively low-level tasks. These routines handle operations such as inputting and outputting bytes, inshaking and outshaking, and sending interrupt bytes. The instruction sequences given in Sec. 3.2 are used heavily in these five routines. Once the five "tools" were developed, the four command driver routines could be designed. These routines are the actual ones called from the main C program when one of the four commands is desired. The four command driver routines and the five low level routines will be included in the same source file for convenience and ease of maintenance. The name of the source file is COM\_EHSI.ASM, which stands for: "Communication Routines for the EHSI Development System." Before the code is entered in the source file, some important commands need to be issued to conform with the interfacing restrictions described in the previous section.

#### COM EHSI.ASM header

Before an 8088 op code is written, the segment and

group names need to be set to comply with the rules of interfacing C and assembly.

The `_TEXT` and `_DATA` segments are assigned the same align type, combine class, class name, and group so that code and data put in the segments are combined with the corresponding C segments at link time. Two variables from the C program are declared to be external words in the `_DATA` segment:

`_SCREEN` is the base address of the `SCREEN` array, which is the array of words sent via interface Command 2.

`_data_pkg` is the base address of the `DATA_PKG` structure, which is the destination for data received through interface command #1.

The `CONST`, `_BSS`, `NULL`, and `_DATA` segments are combined into a group named `DGROUP`, just as the C programs are grouped. Also, the code segment is assumed to be the `_TEXT` segment. The data, stack, and extra segment are all assumed to be the value of `DGROUP`.

The compiler directive `EQU` is used to make the assembly code more readable and easier to maintain. Any constants can be `EQU`ated to an expression. On the first pass of the compiler, the expression is replaced by the constant equated to it earlier. The port addresses, enable and disable values, and error definitions are given expressions, hopefully descriptive of their functions.

The last line of the header opens up the `_TEXT` segment

so that all the following code is placed in the `_TEXT` segment. The line following the last routine in the source file tells the compiler to stop putting code in the `_TEXT` segment.

#### COM\_EHSI.ASM low level routines

`inshake_proc` is a procedure that watches for the DACI to pulse the Z-158 INSHAKE line. Fig. 16 shows the flow of the procedure. Since the line is normally high, the routine waits for the line to go low. If this doesn't occur within a certain amount of time, an error is returned in `ax`. The time that is allowed for the line to go from high to low is controlled by an expression called `INSHAKE_WAIT_LOW`. The value of the expression is defined in the header of `COM_EHSI.ASM`, and the equation to determine the actual time is found in Appendix B. After the INSHAKE line goes low, the routine watches for the transition back to high. An error is returned by `ax` to the calling routine if the line does not go back high within a specified amount of time. `INSHAKE_WAIT_HIGH` controls the length of time to wait for the line to go back high. See Appendix B for more information. If no errors occurred, `NO_ERROR` is returned in `ax` to the calling routine. This procedure is only called by other assembly language routines. Therefore, special entry and exit procedures for this routine are not necessary. A 'return' instruction transfers control back to the calling routine.

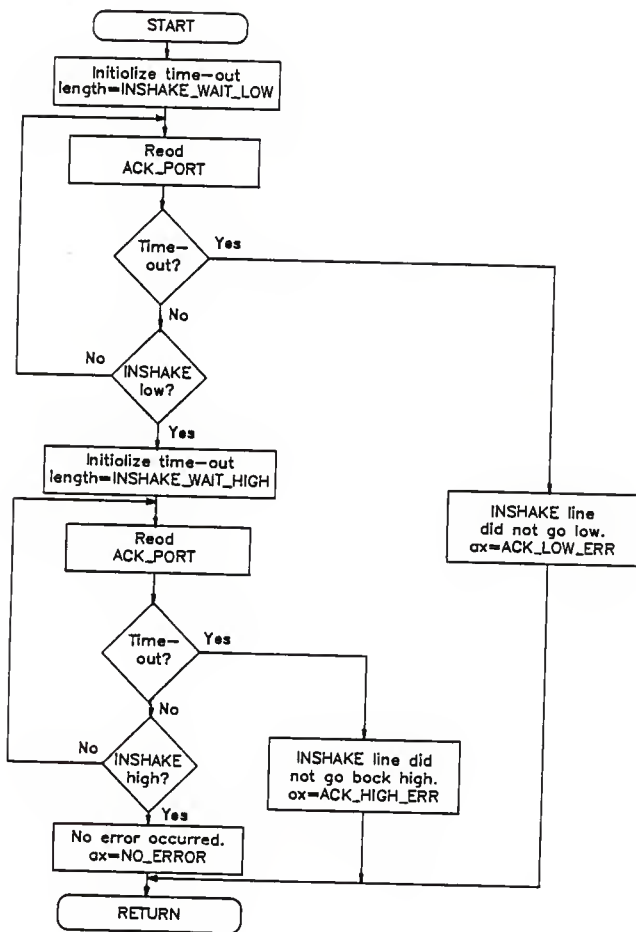

Figure 16. inshake\_proc flowchart.

`outshake_proc` is a procedure that outputs a pulse on the OUTSHAKE line of the Z-158. Fig. 17 shows a flowchart of the procedure. The line is normally high, so the pulse consists of a transition from high to low, and then back high. The time that the line is low is controlled by an expression defined in the header. Errors cannot occur, so nothing is returned. This procedure is only called by other assembly language routines. Therefore, special entry and exit procedures for this routine are not necessary. A 'return' instruction transfers control back to the calling routine.

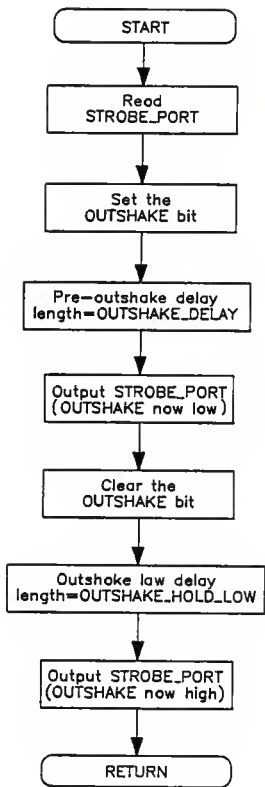

Figure 17. outshake\_proc flowchart.

**input\_byte\_proc** is a procedure that performs the steps necessary to read the data bus. Fig. 18 is a flowchart of the procedure. The data bus is enabled for a read, the read is performed, and the data bus is disabled. **outshake\_proc** is then called to tell the DACI that the read was accomplished. No errors can occur, so an error code is not returned. The byte read from the data bus is returned in **ax**. This procedure is only called by other assembly language routines. Therefore, special entry and exit procedures for this routine are not necessary. A 'return' instruction transfers control back to the calling routine.

Figure 18. `input_byte_proc` flowchart.

`output_byte_proc` is a procedure that outputs a byte to the data bus and then waits for the acknowledge pulse from the DACI on the Z-158 INSHAKE line. Fig. 19 is a flowchart of the procedure. The byte to output is passed to the routine in `al`. The data bus is enabled for a write, and the output byte is put on the bus. `outshake_proc` is called to let the DACI know that a byte is on the data bus waiting to be read. Before disabling the data bus, the routine must wait for the DACI to acknowledge that it read the byte. The procedure `inshake_proc` is called to wait for the acknowledge pulse on the INSHAKE line. If an error occurred in receiving the acknowledge pulse, the error returned from `inshake_proc` is kept in `ax` to be passed to the calling routine. The data bus is disabled after `inshake_proc`. This procedure is only called by other assembly language routines, so the special entry and exit sequences required for calls from C programs are not necessary. A 'return' instruction transfers control back to the calling routine.

Figure 19. `output_byte_proc` flowchart.

`output_int_byte_proc` is a procedure used for interrupting the DACI to initiate one of the four interface command routines. Fig. 20 is a flowchart of the procedure. After enabling the data bus, the interrupt vector passed by the calling routine in `al` is placed on the data bus. To interrupt the DACI, the `IRQOUT` line is pulsed low and back high. The routine must then wait for an acknowledge pulse from the DACI. From the timing diagrams in Sec. 2.2, the DACI can take up to 135 usec to respond to the interrupt pulse. If an acknowledge error occurs, the routine returns an error code to the calling function. If the acknowledge pulse was received without error, a bus check is performed to make sure the DACI is thinking the same thing the Z-158 is. The data bus is cleared by writing `OOH` to it, and then a read is performed to make sure the DACI is not trying to output something. If `OOH` is read in, then no error occurred. If a non-zero byte was read, a bus conflict error is returned to the calling routine. All error checking is completed, and the data bus is disabled. This routine is called only by other assembly language routines, so special entry and exit sequences are not necessary. A 'return' instruction transfers control back to the calling routine.

The five procedures have been coded and can be found in `COM_EHSI.ASM`, Appendix A. The sequences written in Sec. 3.2 are used throughout the routines. Also, the expressions

used for port addresses, output control bytes, and error codes are defined in the header portion of COM\_EHSI.ASM.

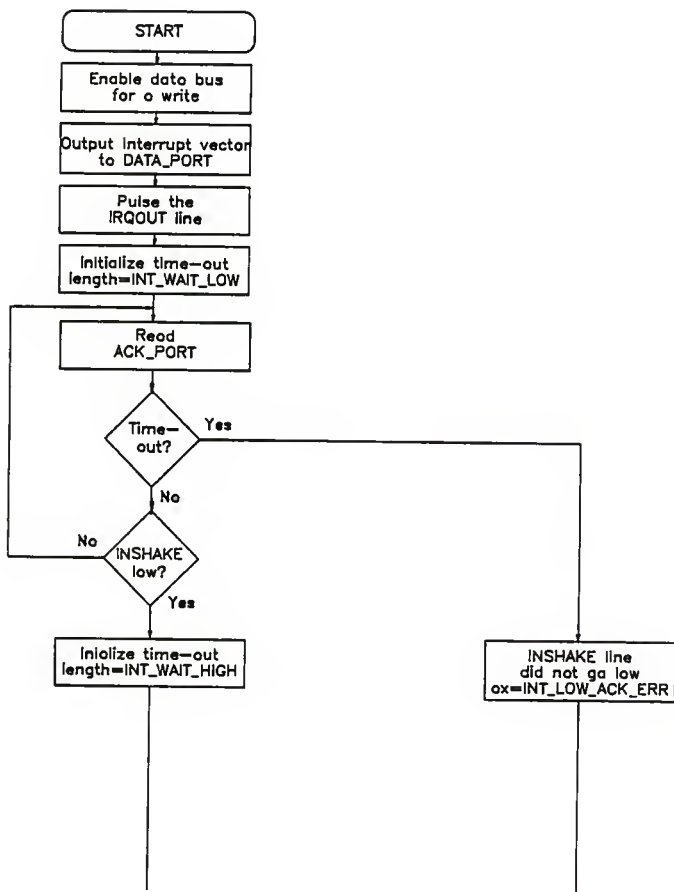

Figure 20. output\_int\_byte\_proc flowchart

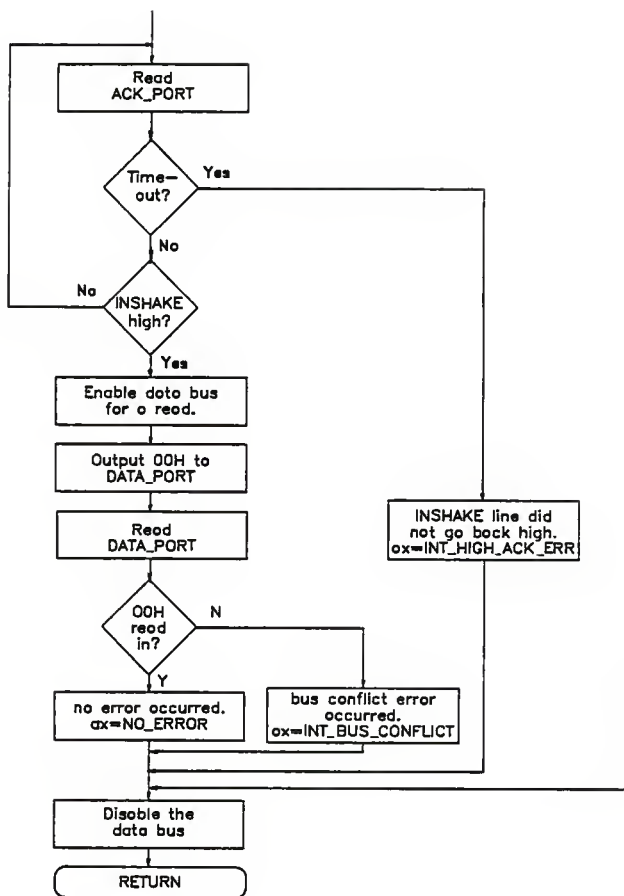

Figure 20. output\_int\_byte\_proc flowchart (cont.)

### COM EHSI.ASM Command routines

The development of assembly-language routines to implement the four commands discussed earlier can now be described. The previous three sections have laid the groundwork for the commands. The timing diagrams (Fig. 4, 5, 6, 7) will be adhered to.

GET\_DATA\_PACKAGE is the procedure called from a C program to execute command #1. The data package is to be transferred from the DACI to the Z-158. A structure named data\_pkg is the final destination of the transferred data. Fig. 21 gives a flowchart of the procedure. Since these procedures are called from C programs, the entry sequence explained in Sec. 3.3 is used. There are no arguments passed to this routine. First, the starting address of the data\_pkg structure is retrieved. output\_int\_byte\_proc is then called to output the interrupt vector 01H to the DACI. If the interrupt was unsuccessful, an error value is returned to the C program via the ax register. The routine will jump to the exit sequence after the error. If the interrupt was successful, the DACI will then start the data transfer. inshake\_proc is called to wait for the pulse signalling the number of bytes to be sent is on the data bus. If an error is returned from inshake\_proc, the error handling procedure is the same as with output\_int\_byte\_proc. The number of entries is checked with the known value, and an error is returned if there is a discrepancy. The routine

reads the data after each outshake pulse is detected, until all the data has been received. Acknowledge pulses are sent on the OUTSHAKE line after each byte is received. After the transfer is complete, the routine must execute the exit sequence described in Section 3.3. This will restore the registers saved in the entry sequence. A 'return' instruction transfers control back to the calling C program.

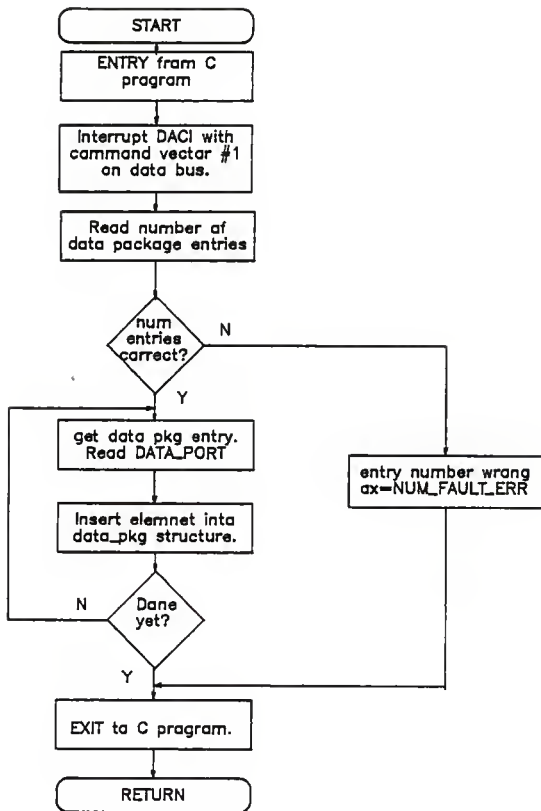

Figure 21. GET\_DATA\_PACKAGE flowchart.

**SEND\_SCREEN** is the procedure called from a C program to execute Command 2. The contents of the SCREEN array are to be transferred from the Z-158 to the DACI. Fig. 22 is a flowchart of the routine. Data words are sent to the DACI until the MSB is OFFH. This is the End of SCREEN signal. As with Command 1, the entry sequence from C programs must be executed since this routine will be called from C programs. After the entry sequence, `output_int_byte_proc` is called to output the interrupt vector corresponding to Command 2. If the interrupt was successful, the data words in SCREEN are sent by bytes, first the MSB and then the LSB. If an error occurs either in `output_int_byte_proc` or `output_byte_proc`, the transfer is suspended and an error code is returned. In any case, before the routine is finished, the exit sequence must be executed to restore the C register to their original values. A 'return' statement then transfers control back to the calling C program.

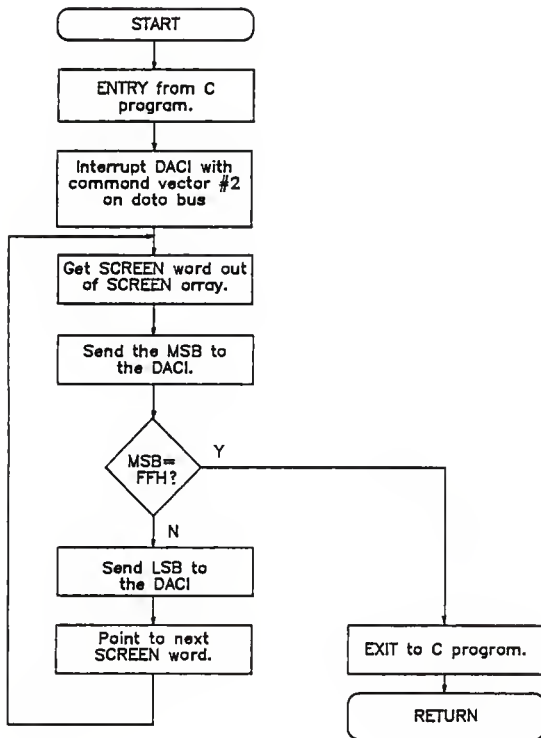

Figure 22. SEND\_SCREEN flowchart.

RETRIEVE\_SCREEN is the procedure called from a C program to retrieve display code that is currently in HP-1345A VGM. Fig. 23 is a flowchart of the procedure. After the entry sequence, which is required for routines being called from C routines, output\_int\_byte\_proc is called to output the interrupt vector corresponding to Command 3. The beginning address of the code to retrieve is found in SCREEN[0], and the end address is in SCREEN[1]. The transfer is then conducted by bytes, first the MSB and then LSB. The retrieved screen code is placed in the SCREEN array starting with the first element. If an error occurs, an error code is returned in ax. If no errors occur, the exit sequence to restore the C registers is executed. A 'return' instruction transfers control back to the calling C program.

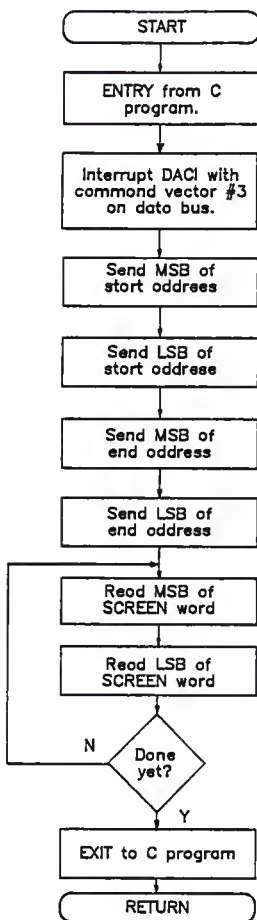

Figure 23. RETRIEVE\_SCREEN flowchart.

**TOGGLE\_ALARM\_SWITCH** is the procedure called from a C program to toggle the ON/OFF status of the alarm. Fig. 24 is a flowchart of the procedure. After the entry sequence is completed, the Z-158 only needs to have `output_int_byte_proc` output the interrupt vector corresponding to Command 4. This will cause the DACI to toggle the alarm state. The exit sequence is executed to restore the C registers, and then a 'return' instruction transfers control back to the C program. If an error was returned from `output_int_byte_proc`, the error code is returned to the calling program.

Figure 24. TOGGLE\_ALARM\_SWITCH flowchart.

The four routines have been implemented in code and can be found in COM\_EHSI.ASM, Appendix A, along with the low level routines. Error codes and other expressions can be found in the header at the beginning of the source file.

### 3.5 Servicing Interrupts from the DACI

Several routines will be presented in this section that deal with the setup, execution of, and restoration of the interrupt environment needed for the EHSI development system. The DACI interrupts the Z-158 by pulsing its IRQOUT line with an interrupt vector on the data bus (see Fig. 2). The Z-158 must suspend its current process and service the interrupt. The routine that does the servicing is installed at startup time into the DOS environment as interrupt OFH, the parallel port interrupt. After the servicing is complete, the suspended process is continued without knowing that the interrupt occurred. It will find out though, when it checks a special stack which holds received interrupt vectors. After a shutdown vector is received, the interrupt environment is returned to its original state. INT\_EHSI.ASM is the assembly-language source file that contains the procedures discussed in this section. Header information will be discussed first, followed by the presentation of each routine.

### INT\_EHSI.ASM header

At the top of INT\_EHSI.ASM is a header similar to the one found in COM\_EHSI.ASM. The segment and group names necessary to allow C and assembly to communicate are assigned according to the guidelines set forth in Sec. 3.3. Since the implementation of the correct segment and group names were done in the COM\_EHSI.ASM header, see its explanation in the preceding section for details. There are some different variables in the header that do need explanation. Args is an expression that holds the offset of the first argument from the base of the stack after entry into an assembly language routine called from a C program. The value is for a small-model program.

Three double-word locations are initialized to 0 and inserted into the \_DATA segment. These locations are for addresses that are saved as static variables, so that the three routines discussed shortly may have access to the same addresses. The values cannot be disturbed by any other routines. The function of each is described below:

int\_OF is where the address of the old interrupt OFH handling routine is stored during operation of the EHSI Development System. At shut-down this address is reinstalled into the interrupt address table.

`int_depth` is the address of the variable in the C program that keeps track of the interrupt vector stack depth.

`int_stack` is the address of the first element of the interrupt vector stack created in the main C program.

### INT EHSI.ASM interrupt routines

`INITIALIZE` is a routine called from the main C program to set up the Z-158 so that interrupts received on the `IRQIN` line can be serviced. The setup includes installing `HANDLER` as the servicing routine. Fig. 25 is a flowchart of the routine. Since this routine is called by a C program, the entry sequence covered in Sec. 3.3 must be executed first. Two arguments are being passed by the calling C program. The last argument, the address of the interrupt vector stack, is popped off the stack first. The address of `int_depth` is popped last since it was the first argument in the call.

Before installing the new interrupt OFH service routine, the old routine's address is fetched from the interrupt vector table and saved for its reinstallation after system shut-down. The new interrupt OF servicing routine, named `HANDLER`, is now installed by placing `HANDLER`'s address in the interrupt vector table in low memory.

Interrupt OF is channelled through an 8259A

Programmable Interrupt Controller (PIC). The PIC receives and prioritizes interrupt numbers 08 through 0F. When the PIC detects an interrupt on one of its lines, if there are no other interrupts pending, the PIC will interrupt the 8088 and pass on the interrupt number. If two interrupts hit the PIC at the same time, the one with the higher priority is serviced first.

The PIC contains an Interrupt Mask Register (IMR) that needs to be changed. The parallel port interrupt must be enabled, and the system clock needs to be ignored during operation of the EHSI Development System. The internal clock interrupts the system over 18 times per second for updating purposes, and the update routine causes timing problems for the Z-158 -to- DACI routines. Therefore, the clock is temporarily disabled via the IMR. The procedure for changing the IMR is explained in Sec. 3.2.

The output control port (Port 037AH) needs to be initialized so that control lines are in their default levels. Line D4 of Port 037AH is the IRQ\_ENABLE line. Sec. 3.2 discusses what it needs to be to enable interrupts on the parallel port interrupt line. Initialization is now complete. The exit sequence necessary for restoring C registers is executed, and a 'return' instruction transfers control back to the calling C program.

Figure 25. INITIALIZE flowchart.

**HANDLER** is the interrupt service routine installed by **INITIALIZE** to service interrupts from the **DACI**. This routine is not executed directly from any C or assembly language routine. The procedure for servicing the interrupt is shown in the flowchart of Fig. 26. All interrupts are turned off immediately in the routine. This will ensure that the interrupt service routine is not interrupted. All registers used by **HANDLER** must be saved before the actual servicing, so that when the suspended process is continued, registers will not be mysteriously changed. The data bus is then read to retrieve the interrupt vector from the **DACI**. The **OUTSHAKE** line is taken low to acknowledge receipt of the vector.

The interrupt vector needs to be placed appropriately in the interrupt vector stack. The current depth of the interrupt vector stack is retrieved and incremented to get the depth of the current vector. Since the vectors are stored as words (2 bytes), the offset of the current vector on the stack will be twice the current depth. After the offset is calculated, the base address of the interrupt vector stack is fetched. The offset is added to the stack base address, and this is the destination for the received interrupt vector.

There are two conditions that affect placement of the received interrupt vector in the interrupt vector stack. If the interrupt vector stack is full, then the current

interrupt is ignored by not placing it in the stack. If the shut-down vector is received, priority is given to it by placing it at the bottom of the stack so that it will be next in line to be serviced.

Since the DACI needs an acknowledge pulse of at least 23 microseconds, a short delay is performed before bringing OUTSHAKE back high. One last duty must be performed before executing the exit sequence. An End of Interrupt signal is sent to the 8259A PIC so it can resume operation. The process, written out in Sec. 3.2, is like an "outshake" pulse to the PIC to acknowledge the interrupt. The registers saved during entry are then restored, and interrupts are turned back on. The 'iret' instruction transfers control back to the suspended process in the exact state it was interrupted in.

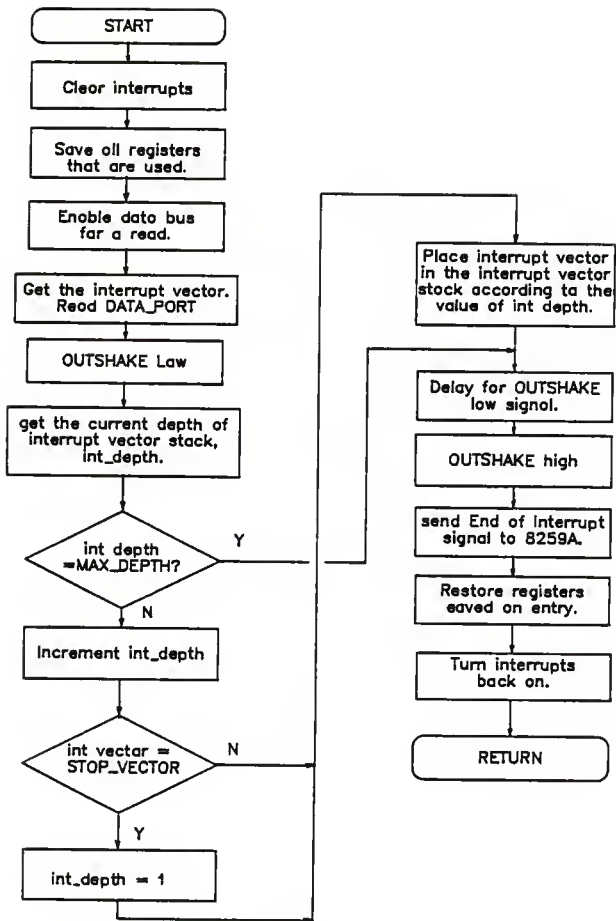

Figure 26. HANDLER flowchart.

**RESTORE** is the routine called to restore the operating environment back to the state before **INITIALIZE** was called. The routine is called after the system shut-down vector is received. Since this routine is called from a C program, the entry sequence for calls from C must be executed first. The old interrupt OF address, saved in **INITIALIZE** as `int_OF`, is reinstalled in the interrupt vector table in low memory. The PIC Interrupt Mask Register is also restored to its original state. The exit sequence to restore the C program registers is executed, and a 'return' instruction transfers control back to the calling program.

Figure 27. RESTORE flowchart.

## IV. THE MAIN PROGRAM

### 4.1 Purpose of EHSI.C

The bulk of this report has been devoted to communication routines, but these would be useless if there were not routines to call upon them. Ehsi.c is the main program that controls the EHSI development system. The main program calls other functions to service the interrupts from the DACI. The routines that are called from ehsi.c use the four commands discussed earlier to talk with the DACI. There are three different classes of functions that are called on receipt of an interrupt vector.

If the start-up or shut-down vector is received, initialization or restoration is performed respectively. If the system clock interrupt is received, a function is called to update the current page. This usually involves a call to GET\_DATA\_PACKAGE, HP-1345A code generation, and then a call to SEND\_SCREEN. If a key number is received, a specific function to service that key is invoked. The key routines will be discussed in Chapter 5. The flow chart of ehsi.c is shown in Fig. 28. The following sections shall explain what goes on in each block of the program.

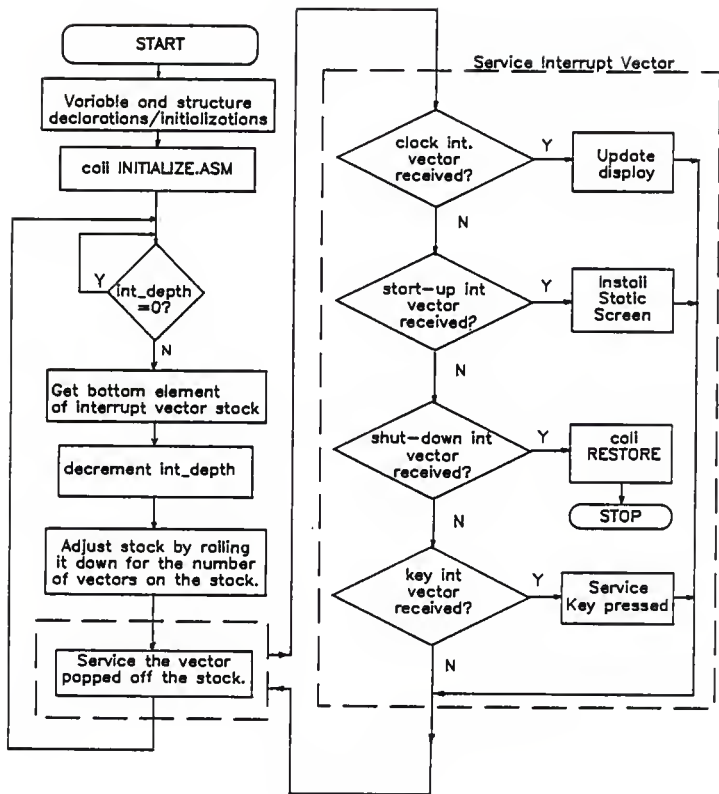

Figure 28. Ehsi.c flowchart.

## 4.2 Declarations and initializations.

The main program is responsible for declaring all the global data used in the system, and it is logical to declare other variables and flags along with them at the beginning of the program. "data\_str.h" is the include file that declares the structures needed. data\_pkg is a structure of type DATA\_PKG which holds the current data package when interface Command 1, GET\_DATA\_PACKAGE, is called. The other two structures defined were added by C. Robertson [3] in his work. The flags defined at the bottom are also his. Notice that data\_pkg has been initialized to zero. This must be done, or else the structure will end up in the c\_common segment where the assembly can't access it. SCREEN[] is initialized to OFFFFH and a size of 1000 words. It is initialized also to insure placement in the \_DATA segment.

After the declarations, but before polling the interrupt vector stack can occur, INITIALIZE is called to set up the environment and install the interrupt service routine, HANDLER. The system is now ready to service interrupts from the DACI.

## 4.3 Ehsi.c Interrupt Servicing.

Ehsi.c polls the variable int\_depth, waiting for it to become greater than zero. A greater than zero value tells the main program that an interrupt vector is present on the stack. The vector is popped and placed in a variable named

int\_number. int\_depth is decremented to tell HANDLER where to put the next vector. If int\_depth is still greater than zero after the decrement, the stack is rolled down to put the next interrupt vector in the queue.

The interrupt vector stack operations are completed for the current vector. The rest of ehsci.c is devoted to determining what course of action to take with the current vector. If the startup vector is received, the static parts of the displays are installed in display memory. If the shutdown vector is received, RESTORE is called to restore the DOS environment back to normal. The program will also terminate. On receipt of the clock interrupt vector, Ehsci.c calls a function to perform an update of the currently displayed page. dat\_pg\_dynamic, nav\_pg\_dynamic, and ils\_pg\_dynamic are three functions written by Robertson [3], that update the dynamic parts of the displays. The final type of interrupt that can be received is the keyboard interrupt. Another decision statement is used to determine which key was pressed and what kind of action is needed. The "service key" block in the flow chart of Fig. 28 will be expanded in the next chapter.

After the interrupt vector has been serviced, the main program returns to polling int\_depth, waiting for the signal that another interrupt vector is on the interrupt vector stack.

#### 4.4 Ehsi.c considerations.

The claim was made earlier that the system is running in an interrupt environment, but it can be seen from the main program, ehsi.c, that some polling does occur. This hardly hampers system performance because all that is polled is one memory location. `int_depth` can be checked every couple microseconds when the interrupt vector stack is empty. When vectors do appear on the stack, they are executed as quickly as the service functions can be completed. In the case where there is more than one vector on the stack, the bottom vector will be serviced first. As soon as that service is completed, the program will return to see that there is still a vector on the stack. The second vector will then be executed immediately.

The program continues until the shut-down vector is received from the DACI. As mentioned before, `RESTORE` is called to return the system to its original state. `Ehsi.c` then terminates.

## V. KEY SERVICING ROUTINES

### 5.1 Purpose of key routines

An important part of the EHSI Development System is the command keyboard. Figure 29 shows how the 6x6 keyboard is set up. Several of the keys deal with changing displays, and some enter flight-related data. Others operate a clock timer implemented by Robertson [3]. A Hewlett Packard style calculator has been implemented by the author as a means of keeping data entries in a stack environment.

Two variables, `x_buffer` and `y_buffer`, are declared in `ehsi.c` as the elements of a small "calculator" stack to be shared by all the key servicing routines. `x_buffer` will be referred to as the first, or bottom element. `Key_buffer` is a character string that keeps track of the current numbers being displayed on the "command line" of the data page. Chapter 7 will show the data page display with the command line in use.

### 5.2 HP-1345A memory organization

In the key routines it is necessary to generate screen code for the display. Two routines, `string_gen()` and `insert()`, were written by Robertson [3] in his work. These routines generate HP-1345A code for character strings, and the code words are placed in the `SCREEN[]` array, but the calling routine is responsible for the address pointer in the display memory. The organization of the HP-1345A

EHSI

Figure 29. 36 Key command keyboard.

"Vector Graphics Memory" for the EHSI development system is presented below.

A memory map of the VGM is shown in Fig. 30. For the EHSI development system, all the static display information is stored in static memory during system operation. Dynamic display information is stored in locations that are often changed. Jump vectors are placed throughout memory to tell the HP-1345A which commands are to be displayed on the screen. At address 000H, a jump vector tells the HP-1345A to display the static parts of one of the display pages. The static sections are installed upon receipt of the start-up interrupt vector from the DACI. After the static display commands are performed, a jump vector transfers the HP-1345A pointer to the dynamic part of the currently displayed page. After these commands are completed, a jump vector points to the command line memory. After the command line is displayed, a jump to the end (FFFH) is performed. The only rule with jump vectors is that a jump vector cannot be jumped to. Therefore, location FFFH contains a NO-OP. The next location (000H) starts the refresh operation again by repeating the process of jumping to static display memory.

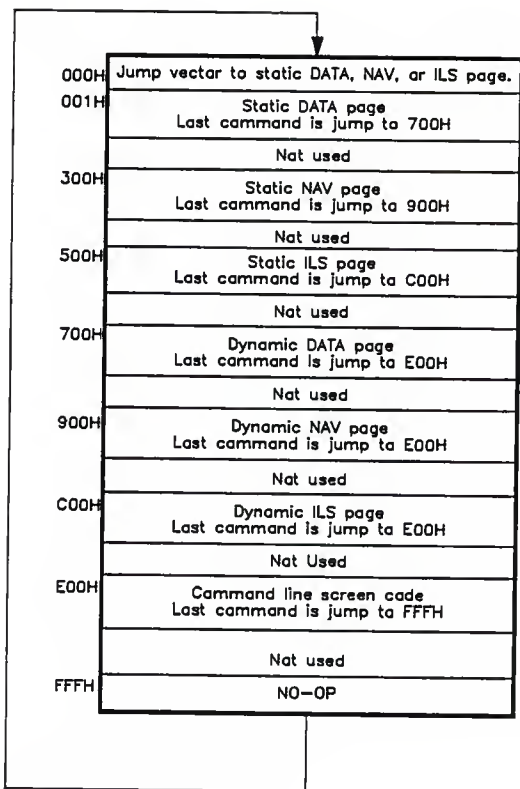

Figure 30. HP-1345A memory map.

### 5.3 Description of key routines

The key servicing routines that the author has implemented are discussed below.

**update\_key\_buffer** is a function called when one of the digits or the decimal point key is hit. The routine determines which key was hit, and then adds the character to the end of `key_buffer`. The updated `key_buffer` is then converted to screen code and sent to the display via `SEND_SCREEN`.

**roll\_stack** is a routine called when the `ENTR` key is hit. This function moves the old value of `x_buffer` into `y_buffer`, and the number currently displayed is put into `x_buffer`. Remember that the number being displayed is actually stored as a character string in `key_buffer`. Therefore, a conversion function is called to convert the character string in `key_buffer` to a number. `key_buffer` is then cleared, and `SEND_SCREEN` is called to clear the command line.

**clear\_stack** is a routine called when the `CLEAR` key is hit. This function clears the contents of `x_buffer`, `y_buffer`, and `key_buffer`. `SEND_SCREEN` is called to clear the command line.

**do\_math** is a routine called when the addition, subtraction, multiplication or division key is hit. The specified math function is performed on the contents of `y_buffer` and `x_buffer`, and the result is placed into

x\_buffer. The result is also placed on the command line via SEND\_SCREEN.

display\_data\_page, display\_nav\_page, and display\_ils\_page are routines that use SEND\_SCREEN to change jump vectors in vector memory so that the respective pages are displayed.

reset\_alarm is a routine that is called when the RESET ALARM key is hit. TOGGLE\_ALARM\_SWITCH is invoked to toggle the ON/OFF state of the alarm on the interface board.

call\_cmd3 is a routine written for the purpose of testing interface command 3, RETRIEVE\_SCREEN. Since the routine is not yet being used in the main part of the system this routine shows the operation of command 3. The start address of the retrieve is taken from y\_buffer, and the end address is in x\_buffer. The call to RETRIEVE\_SCREEN is performed, and the retrieved code is printed on the Z-158 screen.

Fig. 31. shows a flowchart of the decision making being done in the "key service" block of Fig. 28. Routines not explained above have been written by Robertson [3].

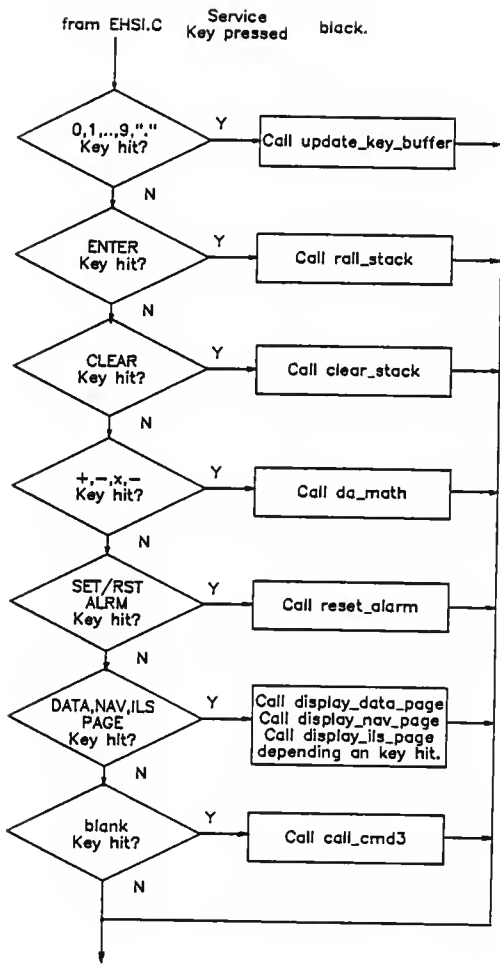

Figure 31. Key interrupt servicing flowchart.

## VI. SOFTWARE CONDITIONING OF INPUT SIGNALS

### 6.1 Flight Data Sampling and Filtering

Filtering of analog flight data has become of interest in the development of the EHSI system. Analog meters tend to have non-linearities and electrical zero-crossing points that are undesirable. A digital filter can be implemented in software to alleviate some of the problems. A filter could also be used to extract information from a signal that would be helpful to a pilot. Therefore, a routine has been written to sample and filter the flight data signals coming from the flight simulator in order to explore the many possibilities.

`flt_ehsi.c` is a routine that allows a user to sample and filter a selected element of the `DATA_PKG` structure. The user must enter the desired filter order and coefficient values in an include file named `flt_ehsi.h`. `Ehsi_filter` is the function called by `flt_ehsi` to implement the filter. The executable file, `flt_ehsi.exe`, is created by issuing the command `MAKE FLT_EHSI`. After the executable file is created, the program is run with the flight simulator operational.

The user will be prompted to enter a number corresponding to the data element he wishes to sample. He will then enter the number of samples to take. The program will prompt him to enter the names of the files in which to

place the unfiltered and filtered data streams. After running the program, the user can upload the data files to the VAX and run a program named CONVERT.FOR to convert the data file from IBM-PC format to VAX-VMS format. RALPH2, a signal analysis program, can then be run to look at the data files. A number of functions can be invoked in RALPH2, one of them being PLOT. As an example, VERTICAL\_SPEED was sampled at 2 Hz and filtered by a fourth-order moving average filter. The two data files created were uploaded to the VAX via KERMIT, converted to VAX format via CONVERT, and plotted by the FANCY PLOT function in RALPH2. The resultant plot is shown in Fig. 31. The lowpass nature of the filter is evident from the way some of the sharp peaks were smoothed out.

Using this method of sampling and filtering data signals from the flight simulator, some practical applications are looked at in the next two sections.

Figure 32. VERT\_SPEED data sample.

## 6.2 A Low-pass filter for GLIDESLOPE

The GLIDESLOPE line coming out of the simulator was sampled at 20 Hz. for the purpose of extracting trend information. It was found, though, that a considerable amount of noise was present in the signal. The top graph of Fig. 33 shows the sampled data. A digital low-pass filter consisting of a ninth-order moving average filter was built to condition the signal. As can be seen by the bottom graph of Fig. 33, most of the noise has been removed, and the signal seems to have the same characteristics as the raw data.

This averaging process may be used on any of the data\_pkg signals. The conditioned signals do not have the sudden changes that make displays "flicker", and the pilot can obtain more accurate flight data.

Figure 33. Low-pass filtered GLIDESLOPE.

### 6.3 A Differentiator for CDI and Glideslope

Two signals, CDI and GLIDESLOPE, are critical during the performance of an ILS approach. The trends of these two data streams could give the pilot information about the tendencies of the airplane to deviate from the approach path. Therefore, a digital filter differentiator was designed to extract this information.

A "low-noise" differentiator given in [5] has the following form:

$$3 \sum_{k=-N}^{k=N} k \frac{x(n-k)}{N(N+1)(2N+1)}$$

Setting N equal to 3, the coefficients were found to be:

$$y(n) = -.107x(n+3) - .0714x(n+2) - .0357x(n+1) \\ + .0357x(n-1) + .0714x(n-2) + .107x(n-3)$$

To force the filter to be causal, a time delay of three periods must be introduced. If a filter is operating in real-time, it cannot use input values that have not occurred yet. Such is the case with the  $x(n+)$  components. This does introduce some error into the differentiation, since the "true" result is always 3 periods late. If sampling rates are sufficiently high, the delay is unnoticeable in the cockpit. The digital differentiator used in the EHSI development system is written out below:

$$y(n) = -.107x(n) - .0714x(n-1) - .0357x(n-2) \\ +.0357x(n-4) + .0714x(n-5) + .107x(n-6)$$

The CDI signal was sampled and filtered by the differentiator. The two plots are shown in Fig. 34. The differentiator did a good job, but it magnified the small amount of noise present with the input signal. The output of the differentiator was then averaged and plotted in Fig. 35. The averaged signal gives a good indication of the trend of the CDI.

The averaged GLIDESLOPE signal found in Sec. 6.2 was also filtered by the differentiator. The results are shown in Fig. 36. The derivative of the averaged signal gives a good indication of the trend of the GLIDESLOPE. The approach taken here is different than the previous one used in differentiating CDI, but the two results are similar. As expected, though, the average of the differentiated signal (CDI) was smoother than the differentiated average (GLIDESLOPE).

With trend information available, an indicator can be placed on the ILS page to show the pilot his trend.

#### 6.4 Filtering Considerations

It is worth noting some considerations concerning the filtering of flight signals. The EHSI Development System currently has a maximum refresh rate of 2 Hz., and a sampling rate this low makes real-time digital filtering

somewhat limited. Increasing speed by changing processors will be necessary to get the sampling rates higher so that useful information can be obtained. There will undoubtedly be an abundance of noise present in the cockpit, so low-pass filtering and shielding will become important. As was shown in the plots, noise shows up quite readily when differentiating, so a differentiator with a cut-off may be needed to smooth the differentiated signals.

A simple way of displaying trend information with the differentiated CDI and GLIDESLOPE signals is to treat one as the real and the other the imaginary part of a complex number. The phase and magnitude of the complex number could be used to display an arrow with variable length that pointed according to the phase value. The length of the arrow could show how much of a change is occurring.

Figure. 34 Derivative of CDI.

Figure 35. Averaged derivative of CDI.

Figure 36. Derivative of averaged GLIDESLOPE.

## VII. THE EHSI DISPLAY PAGES

Using the routines developed in this research, C. Robertson [3] has written functions in C to implement the different pages on the HP-1345A. He has also written routines to service key presses and operate alarms. The three display pages, Data page, NAV page, and ILS page, were proposed by Lagerberg [2]. Robertson has implemented variations of these concurrently with the research conducted in this thesis. Each page shall now be discussed briefly.

### 7.1 Data page

The Data page is designed to give general flight data and provide for a page to enter communication frequencies, timer values, and other keyboard entries available. Fig. 37 shows the proposed Data page [2]. Also available are engine statistics and weather information.

### 7.2 NAV Page

The Navigation page is designed to offer a view to the pilot of where he is relative to navigational fixes. A type of "road map" is displayed on the screen showing the plane relative to VOR's, NDB's, and preprogrammed waypoints. Fig. 38 shows the proposed NAV page [2]. The compass rotates as the plane changes course, and distance and direction information is constantly updated.

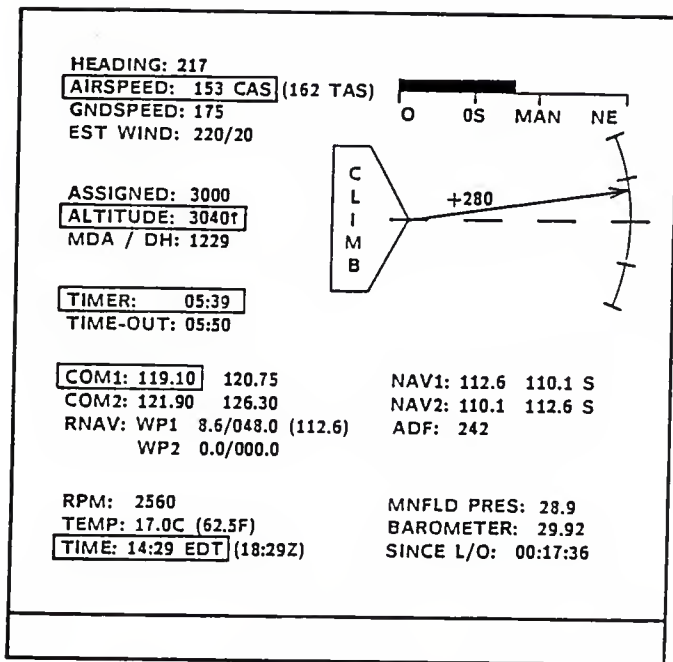

Figure 37. Proposed Data page.

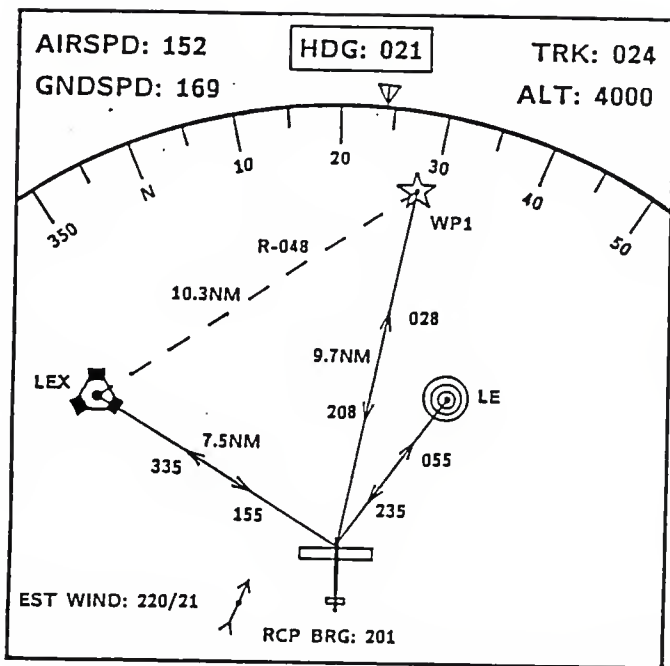

Figure 38. Proposed NAV page.

### 7.3 ILS Page

The Instrument Landing System (ILS) page gives information for an instrument landing. The GLIDESLOPE and CDI are used to derive the airplanes position relative to the landing system beams being projected from the threshold of the runway. Fig. 39 shows the proposed ILS page [2]. The tunnel shows the "walls" to stay within so that a landing can be made. As the plane nears the runway, the runway grows and the tunnel shortens until the runway is in sight for the pilot. A trend indicator is proposed in the box below the heading. The differentiated CDI and GLIDESLOPE signals would be used to point the arrow in the correct direction.

Figure 39. Proposed ILS page.

## VIII. CONCLUSIONS

In this thesis, a number of algorithms have been presented that establish communications between an interface and a host computer of an EHSI development system. The algorithms have been implemented on a Zenith 158 personal computer, and the communication routines were interfaced with C. As a result, a system has been designed to operate an EHSI development system. Display update functions have been written by another team member, and the communication routines are used extensively within the functions. The routines seem to be "bug free" and hard to "lock up".

A main program for the system was presented. This program coordinates interrupt vector servicing with the communication routines.

Key routines were presented that service key presses in a calculator-style environment. Throughout these routines, the procedure for using the interface command routines is found.

Several flight simulator signals have been filtered, and useful trend information was obtained from the CDI and GLIDESLOPE signals. The program `Flt_ehsi.c` was designed so that future project members can sample and filter flight signals.

The research covered in this thesis has contributed to an EHSI Development System which is presently functional. The system display pages are close variations of the ones proposed, and the 2 Hz. update frequency enables real-time viewing of the display pages.

### **Recommendations for Future Work**

There is still much to be done before a prototype can be built and tested. A few suggestions are listed below, and more can be found in [2] and [3].

After a sufficient amount of development and testing of the current display pages, work should be accomplished to determine how the current host computer's work will be accomplished in the cockpit of an airplane. This will most likely entail the design of a dedicated processor board. A processor will be required that enables more than a 2 Hz. screen update rate. The board should be compatible with the DACI, and provisions should be made to make it easy to modify the memory on the board. This would be handy during flight testing. A non-Intel processor will probably be used, and it is hoped that the detailed algorithms presented in this thesis will aid in the writing of code for a different processor.

A very worthwhile project would be a display driver interface that operated on short codes from the host, and translated them to the HP-1345A. This would take many time-

consuming tasks away from the host so that it could increase the update rate, or generate more detailed pages.

The ATC-610 flight simulator has a wealth of information readily available in the form of navigational aids. A data base could be designed that stored information on NDB's, VOR's, and obstacles that are normally presented on flight maps. The main program should then be able to access information on objects that are within a certain radius of the airplane. Using the data base information, the page update functions could then show detailed information of the NDB's, VOR's, and obstacles such as radio towers in the area.

There are many more tasks left to be accomplished before the EHSI is installed in an airplane. For the time being, it is exciting to see one operating from a simulator. With a new set of team members and fresh ideas, it is hoped that the EHSI system can continue to progress towards the cockpit.

\*\*\*\*\*

;

;\* SOURCE\_FILE: COM\_EHSI.ASM

;

;\* FUNCTION: SEND\_SCREEN

;

;\* DESCRIPTION: This procedure is used to send the contents  
;\* of the SCREEN array to the HP-1345A through  
;\* the DACI via command #2.

;

;

;\* EXTERNAL  
;\* VARIABLES:

;

;\* SCREEN (word)  
;\* C program array that holds the words  
;\* to be sent. The end of the array is  
;\* detected when the MSB of a word is FFH.

;

;\* RETURN  
;\* REGISTER:

;

;\* ax (integer)  
;\* error status according to the following:  
;\* NO\_ERROR: Normal completion.  
;\* INT\_LOW\_ACK\_ERR: DACI did not  
;\* acknowledge interrupt.  
;\* INT\_HIGH\_ACK\_ERR: DACI did not bring  
;\* ack line back high  
;\* after interrupt.  
;\* ACK\_LOW\_ERR: Acknowledge line did  
;\* not go low.  
;\* ACK\_HIGH\_ERR: Acknowledge line did  
;\* not go back high after  
;\* going low.  
;\* other: Other error code.

;

```
*****
;*
;* SOURCE_FILE:  INT_EHSI.ASM
;*
;* FUNCTION:     INITIALIZE(&int_depth,&int_stack)
;*
;* DESCRIPTION:  Performs initialization of the EHSI
;*               developement system. An interrupt handler
;*               called HANDLER is installed, and the
;*               system interrupt environment is altered
;*               to suit the needs of the main program.
;*               This function is the first function
;*               that the main program should invoke.
;*
;* ARGUMENTS:
;*
;*   &int_depth
;*       is the address of a variable used to tell
;*       the main program how deep the interrupts
;*       are stacked.
;*
;*   &int_stack
;*       is the address of the base of the stack
;*       where interrupt vectors are stored while
;*       the main program cannot keep with the
;*       interrupts from the DACI.
;*
;* RETURN:       None.

### PROGRAM MAINTENANCE

Compiling and Linking . . . . .	170
Adjusting Pulse-widths and Time-out delays . . . . .	176

## Compiling and Linking

To create an executable file to operate the EHSI Development System, issue the following command from within the directory containing all the source files:

```
MAKE EHSI <RETURN>
```

This will invoke Microsoft's MAKE utility [6]. The required MAKE file is included starting at page 171. MAKE looks at the target file and determines whether a dependent file has been modified. If one has, then the commands on the lines following are performed until a blank line is encountered. The compile and link are performed in the process of executing MAKE.

```

## Adjusting Pulse-widths and Time-out delays

Expressions are defined in the header of com\_ehsi.asm that control the widths of output pulses and the maximum amount of time to wait for an acknowledge pulse. Each expression is discussed below, and the equations assume that the Z-158 is operating at 8MHz.

INSHAKE\_WAIT\_LOW controls the maximum amount of time that INSHAKE\_PROC will wait for a high-to-low transition on the DACI OUTSHAKE line. The time in microseconds is found from the following equation:

$$\frac{27 + (\text{INSHAKE\_WAIT\_LOW} - 1) * 34}{8}$$

OUTSHAKE\_WAIT\_HIGH controls the maximum amount of time that INSHAKE\_PROC will wait for the DACI OUTSHAKE line to return back to high after going low. The time in microseconds is found from the following equation:

$$\frac{18 + (\text{INSHAKE\_WAIT\_HIGH} - 1) * 34}{8}$$

OUTSHAKE\_DELAY controls how long OUTSHAKE\_PROC waits before actually pulsing the OUTSHAKE line. The timing diagrams in Sec. 2.2 show that the DACI needs time to get ready to watch for a pulse on the Z-158 OUTSHAKE line. The following equation gives the time in microseconds:

$$\frac{43 + (\text{OUTSHAKE\_DELAY} - 1) * 18}{8}$$

OUTSHAKE\_HOLD\_LOW controls the time that OUTSHAKE\_PROC

keeps the Z-158 OUTSHAKE line low. The following equation gives the time in microseconds:

$$\frac{18 + (\text{OUTSHAKE HOLD LOW} - 1) * 18}{8}$$

INT\_WAIT\_LOW controls the length of time that the Z-158 will wait for the DACI to pulse the OUTSHAKE line after being interrupted by OUTPUT\_INT\_BYTE\_PROC. The time in microseconds is given below:

$$\frac{22 + (\text{INT WAIT LOW} - 1) * 34}{8}$$

INT\_WAIT\_HIGH controls the time that OUTPUT\_INT\_BYTE\_PROC waits for the interrupt acknowledge pulse from the DACI to go back high after going low. The time in microseconds is given below:

$$\frac{16 + (\text{INT WAIT HIGH} - 1) * 34}{8}$$

## APPENDIX C

### MODIFICATIONS

Z-158 Parallel Port Modification . . . . .	179
DACI External Clock Switch Addition . . . . .	181
DACI IRQOUT and IRQIN lines addition . . . . .	183

## Z-158 Parallel Port Modification

The Z-158 parallel port was modified to enable data reads from the data bus. The output latch of port 0378H was always enabled previously, thus only allowing the latch to be read instead of data coming through the external parallel port connection. As can be seen in Fig. 40, the RPA line was inverted and sent to the output latch's enable pin to correct the problem. This forces the output latch to go into the high impedance state while the read is occurring, so that the data on the parallel port is read instead of the latch. The bottom figure is the corrected circuit, and the top diagram shows the original circuit. The modification was accomplished by adding an inverter chip to the top of the output latch.

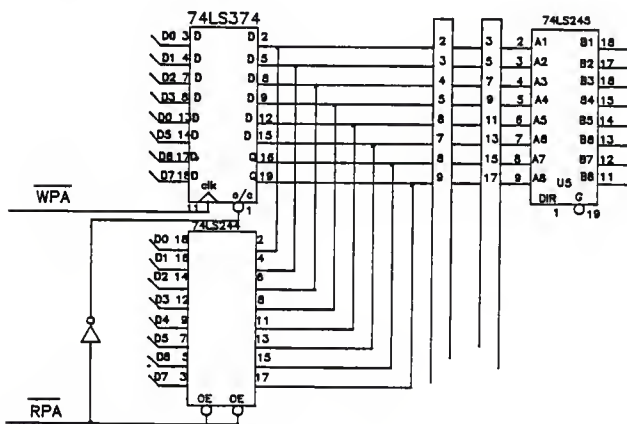

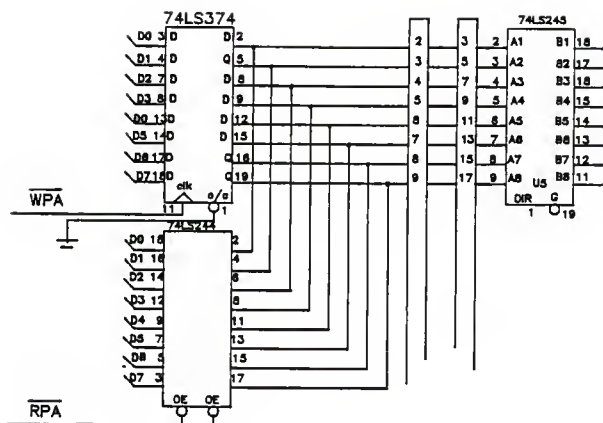

Figure 40. Z-158 Parallel Port Modification.

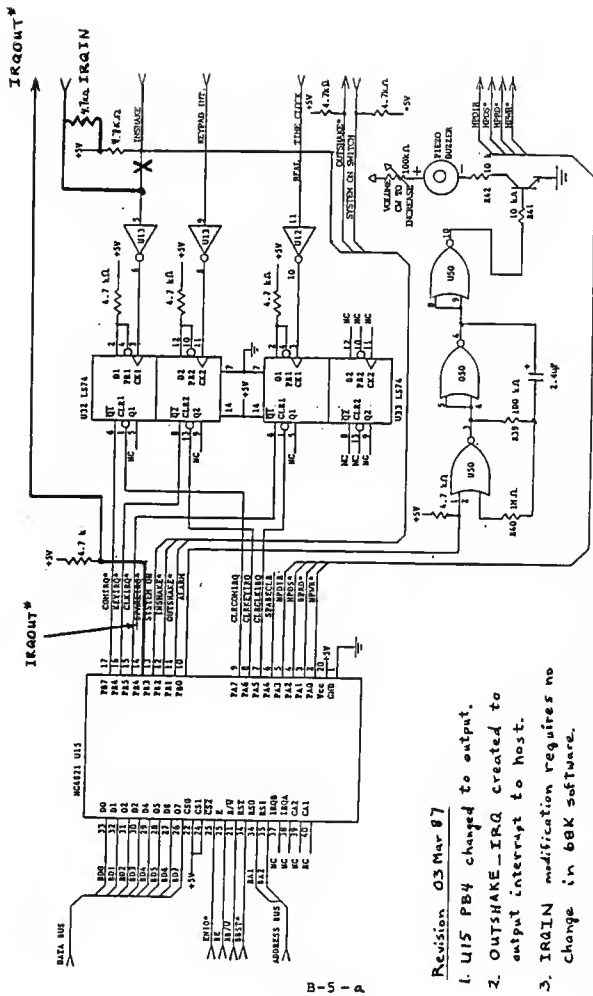

### DACI External Clock Switch Addition

In order to run the EHSI system at variable speeds, a switch was added to the DACI that gives the user the choice of using the system clock or adding an external signal generator. The line connections changed are seen in Fig. 41. The benefit of this modification was apparent in the filtering section, where greater than 2 Hz updates are required. The system can also be pushed to its limit by adjusting the frequency of the signal generator, thus finding the maximum update rate that the system can keep up with.

#### DACI IRQOUT and IRQIN lines addition

Two lines were added to the DACI that helped separate interrupt requests and handshaking sequences. Figs. 42 and 43 show the change of connections made on the DACI. A routine was added to the DACI software that pulses the DACI IRQOUT line. Dedicated interrupt request and receipt lines are necessary to alleviate timing problems. Interrupts were being missed, and OUTSHAKE pulses were being mistaken for interrupts before the IRQ lines were added. The modification has greatly reduced the number of acknowledge errors and bad interface commands between the Z-158 and the DACI.

CONTROL PIA AND ALARM HORN (PIA #1)

Revision 03 Mar 87

1. U15 PB4 changed to output.
2. OUTSHAKE-IRQ created to output interrupt to host.
3. IRQIN modification requires no change in 68K software.

AN ABSTRACT OF A MASTER'S THESIS

Submitted in partial fulfillment of the  
requirements for the degree

MASTER OF SCIENCE

Department of Electrical Engineering

KANSAS STATE UNIVERSITY

Manhattan, Kansas

1987

Assembly-language routines are presented that establish communications between the host computer (Zenith-158), and the smart interface of an electronic horizontal situation indicator (EHSI) development system. Communications are accomplished in an interrupt environment supported by a handshaking protocol. The main program, written in C, is presented as the controlling program for the EHSI system. The main program and communication routines are interfaced together. Functions are presented that service key presses of the system keypad. Flight simulator data is sampled and differentiated, via digital filtering, to extract airplane trend information. User guidelines and maintenance information for the communication routines are given.
