Abstract

The shortage of clean, usable water is a global problem (Millennium Ecosystem Assessment, 2005). As much as 80% of the world's population has been reported to be in areas of high water security risk due to a convergence of factors, such as watershed disturbance, pollution, water resource development and biotic factors (Voeroesmarty et al., 2010). Water reuse technologies are a potential solution to this problem. However, implementation of treatment technologies for improved water reuse require rapid, effective monitoring techniques capable of insuring treatment quality. Fluorescence spectroscopy has shown potential for wastewater treatment monitoring due to its sensitivity, selectivity, and capacity to be employed in-situ. Online fluorescence data and full fluorescence excitation-emission matrices coupled with parallel factor analysis (PARAFAC) were employed to evaluate the treatment performance of a membrane bioreactor (MBR) at Fort Riley, KS. Specific research goals were to evaluate the effectiveness of fluorescence for monitoring wastewater treatment of a full scale MBR and to determine the contamination detection limit of fluorescence techniques in a non-potable reuse scenario. Study results revealed a two-stage startup period, the first 60 days indicated membrane cake layer formation and the first 90 days showed signs of oxic tank maturation. Fluorescence was found to be effective at monitoring carbon concentration trends throughout the MBR system, and showed preferential removal of protein-like dissolved organic matter (DOM) throughout the study period, and an increase in biodegradation of DOM as the oxic tank matured. A ratio of the humic-like fluorescent components to the protein-like fluorescent components was found to correlate to TOC removal ($R^2 = .845$, $p < .001$). Also, fluorescence was able to detect contamination in the effluent at the 0.74-1.24mg C/L level using two wavelength pairs,

indicating that effective real-time monitoring for contamination can be accomplished with minimal instrumentation and post-processing of data.

Acknowledgements

The author would like to thank Dr. Stacy Hutchinson, Dr. Natalie Mladenov, and Dr. David Steward for their guidance and patience throughout this work. Not to mention the comradery and aid of my fellow graduate students. I will remember this time of my life fondly. Thank you for your friendship, Kelsey. The project was funded by the EPA – Net Zero Initiative.

Dedication

This work is dedicated to my wife, Meagan, and my baby girl. Your love and support
have proven invaluable.

Lord, bless you both.

The heavens declare the glory of God, and the sky above proclaims his handiwork.

Day to day pours out speech, and night to night reveals knowledge.

There is no speech, nor are there words, whose voice is not heard.

Their voice goes out through all the earth, and their words to the end of the world.

Chapter 1 - Introduction

Water reuse and reclamation technologies have tremendous potential to make a large supply of previously used water available for reuse, stretching our limited resources further and reducing our impact on fresh water supplies. While water reuse and reclamation are widely practiced across the globe, the current 9.8 million cubic meters per day of reused water in the United States makes up only a small percentage of the total effluent generated (Miller, 2006).

Despite the potential benefits of water reuse, reuse systems are not yet widely implemented in the US. This is due, in part, to the risk related to water reclamation technology failures and heightened perceived risk by reclaimed water consumers. In order to decrease infrastructure costs, water reclamation systems are often installed near the location of source water and the point of reuse. Failure in these reclamation systems poses an elevated threat due to the lack of travel time from treatment back to consumers (Hambly, Henderson, Baker, Stuetz, and Khan, 2012; Henderson et al., 2009). In addition to the actual risk involved, failure in these systems feed in to negative public perception of reused water and provide justification for opponents of water reuse systems. These issues present a need for acute, real-time water monitoring to increase public confidence as well as to defend the public from system failures. Acute, real-time monitoring of these systems can improve their safety by detecting lower levels of contamination and providing timely system failure information, allowing for appropriate action to protect the public.

Fluorescence based techniques are very sensitive and may be employed inline in water treatment systems and can therefore meet this need (Henderson et al., 2009), however more research needs to be done to determine their effectiveness and limitations in different water treatment contexts.

Research Objectives

In response to the need for improved water treatment monitoring, the goals of this study are to: evaluate the effectiveness of fluorescence based techniques to monitor wastewater treatment throughout a full scale membrane bioreactor (MBR), including correlation to carbon removal, and determine the contamination detection limit of fluorescence techniques in a non-potable reuse scenario.

Significance of Work

MBRs are a widely used for water reclamation, but are prone to membrane fouling (Le-Clech, Chen, and Fane, 2006). Fouling leads to increased operation costs as the membrane must be replaced or cleaned periodically. Current efforts to reduce fouling involve optimizing MBR operation and understanding the mechanism of fouling. Fluorescence techniques have an advantage over commonly used bulk carbon measurements for this application in that they provide information about the types of carbon compounds present in the wastewater, rather than only the amount of carbon. Therefore, fluorescence based techniques can be used to further understand MBR operation and fouling mechanisms in order to reduce membrane fouling and the related costs.

Fluorescence techniques have been used to detect contamination in clean water sources from wastewater (Hambly et al., 2010; Stedmon et al., 2011), and the sensitivity of monitoring techniques in drinking water systems has been reported (Hambly et al., 2010; Stedmon et al., 2011). However, no work has been done to determine detection limits between non-potable recycled water and wastewater, which has a much smaller difference between influent and effluent quality. This study offers detection limits of several fluorescence based measurements in a non-potable context. Since direct measurement of pathogens often involve plating and growing

the pathogens, immediate online detection of contamination allows for appropriate action to be taken to protect the public from harm much more quickly.

Fluorescence has also been shown to correlate with DOC removal by different common treatment processes and in different environments (Baghoth, Sharma, and Amy, 2011; Hur and Cho, 2012; Shutova, Baker, Bridgeman, and Henderson, 2014), and with biodegradability (Yang, Shin, and Hur, 2014). This study contributes to this body of knowledge by examining the relationship TOC removal and fluorescence parameters.

Chapter 2 - Literature Review

State of Water Resources

The world's water resources are in jeopardy, both in terms of quality and quantity. The National Academy of Engineers (NAE) identified providing access to clean water to be a grand challenge for engineers in the twenty first century (National Academy of Engineers, 2016). It is not only those in the arid regions that are facing challenges in sustaining a supply of potable water. As much as 80% of the world's population has been reported to be in areas of high water security risk (Voeroesmartly et al., 2010). Communities around the world are facing water related sustainability challenges due to increased demand, contamination of ground and surface water, and dependence on single sources of supply (Henderson et al., 2009; Miller, 2006). The Millennium Ecosystem Assessment reports that water withdrawal from rivers and lakes for irrigation, household, and industrial use has doubled over the last forty years (Millennium Ecosystem Assessment, 2005). In addition to the issues caused by water resource management and increasing population, the situation is exacerbated by the changing climate. Unpredictable rainfall patterns and periods of increased drought are moving communities to create sustainable water management plans while still meeting customer demand (Henderson et al., 2009; Miller, 2006).

Wealthy nations have largely been sheltered from the impacts of diminishing water resources through tremendous wealth and abundance of natural resources (Voeroesmartly et al., 2010). Wealthy nations have the ability to mitigate water security risk through investment in infrastructure that other nations cannot afford. For example, much of the U.S. and European population are in areas of high water security risk based on the convergence of watershed disturbance, pollution, water resource development, and biotic factors (Voeroesmartly et al.,

2010). This risk is highly mitigated by considerable water infrastructure investment, shifting the risk of wealthy areas of the globe from the 90th percentile down to the 5th.

This being said, there is an increasing trend in water shortages and water quality issues here in the U.S. For example, the drinking water supply of Wichita Falls, Texas fell from 90% to 20% capacity from 2010 to June, 2014 (City of Wichita Falls, TX, 2014). In response, the town of 150,000 has implemented a Direct Potable Reuse Program. The measure is temporary until a \$35 million Indirect Potable Reuse project is completed within the next few years (City of Wichita Falls, TX, 2014).

More recently the city of Flint, Michigan experienced highly contaminated water entering their drinking water supply (CBS News, 2014). Corrosive water in the pipes dissolved lead into residents' drinking water. This was the result of an economic decision to shift the town's water supply from clean but expensive Lake Huron to the Flint River, an infamously contaminated tributary of the lake. Just seventy miles from the largest group of fresh water bodies on earth, the town of Flint has been unable to provide its citizens with fresh water due to industrial practices detrimental to environment. Reflecting on the state of American water infrastructure, the American Water Works Association's *Buried No Longer: Confronting America's Water Infrastructure Challenge* reports that restoring and expanding the existing drinking water infrastructure in the U.S. will cost at least 1 trillion USD over the next 25 years (Raucher, Cromwell, and Reynolds, 2012).

Water Reuse

Water reuse and reclamation technologies have potential to make a large supply of previously used water again available for use, stretching our limited resources much further than before and reducing our impact on fresh water supplies.

While water reuse and reclamation are practiced widely across the globe, the current 9.8 million cubic meters per day of reused water in the United States makes up only a small percentage of the total effluent generated (Miller, 2006). According to Shannon et al. (2008), agriculture returns 30-40% of its wastewater to the environment, while industrial uses return 80-90%, power generators return 95-98%, and public and municipal users return 75-85% **Table 1**. The majority of this water is returned to the environment after a single use. While **Table 1** neglects to account for the situation specific barriers that may arise, such as distance from treatment location to reuse or space limits for additional infrastructure, it is clear the tremendous impact widely implemented water reuse can have on freshwater resources.

Category	Freshwater withdrawals by use (Mm ³ day ⁻¹) ¹	% return by use ²	Volume available for reuse (Mm ³ day ⁻¹)
Agricultural	478.5	35%	167
Industrial	80.3	85%	68
Power generation	609.5	96%	588
Public and municipal	172.6	80%	138
Total	1340.9	71%	961

Table 1 - Reusable percentage of freshwater withdrawals by water source

1 - (Maupin et al., 2014)

2 - (Shannon et al., 2008)

Consider freshwater withdrawal for power generation as an example. Since 2005, water withdrawals for power generation have decreased by 20%, yet thermoelectric water withdrawals still account for 45.5% of the total daily withdrawals for the U.S. (Kenny, Barber, Hutson,

Linsey, and Maupin, 2009; Maupin et al., 2014). This decrease reflects the shift in cooling technologies from open-loop systems to the much more efficient closed-loop recirculating systems and, as this trend continues, replacing the necessary coolant water with reclaimed water becomes more possible.

An obstacle to reuse is the additional infrastructure to transport reclaimed water to its location of use, but this can be overcome by locating power plants and wastewater treatment plants near each other. This is difficult because many municipal wastewater treatment plants are large centralized systems. These systems have been in place for long periods of time and the piping is buried under city blocks, making it very difficult to replace or improve upon. Building new thermoelectric power plants and wastewater treatment plants near one another reduces the need of much additional infrastructure. This practice has been increasingly common as freshwater resources are becoming scarcer and as restrictions are being placed on their use (Li, Chien, Hsieh, Dzombak, and Vidic, 2011). Li et al. (2011) estimate that if power plants switch to recirculating systems, ~50% by capacity of existing power plants in the U.S. could meet their cooling water demand with municipal wastewater from a treatment plant located within a 10 mi. radius. Increasing the radius to 25 mi would allow for 76% of existing power plants to meet their water cooling needs with treated wastewater.

If this practice were implemented, there would be a significant improvement in water security in the affected regions. The study by Li et al. (2011) only considered the impact of water recycling in regard to thermoelectric power plants, this practice could be implemented to provide recycled water for a variety of uses near appropriate sources of recyclable water.

Communities are implementing smaller, decentralized systems in new developments to stem the increasing wastewater load on their existing centralized system, or simply to reach rural

areas with no centralized water treatment system (Hambly, Henderson, Baker, Stuetz, and Khan, 2012; Massoud, Tarhini, and Nasr, 2009). With the installation of these small systems, it is possible to install piping back into residential or commercial areas to return the water for non-potable use, thus reducing the cost of installing the long distance piping to reach a centralized water treatment facility. In general, proximity between the source of reclaimed water and the location of its use is valuable and developing this precedent opens the door for more patterns of water reuse to emerge.

Membrane Bioreactors

An important treatment technology for water reuse is the membrane bioreactor (MBR). This technology was first reported in 1969, but has since remained in the spotlight for its potential for creating high quality effluent (Smith, Di Gregorio, and Talcott, 1969). This process combines the biological digestion of activated sludge methods with microfiltration or nanofiltration to replace sedimentation. These technologies have the capability to produce high quality effluent that is immediately ready for some reuse applications, such as irrigation, or as a pretreatment for RO systems to return the water to potable quality (Shannon et al., 2008).

The commonly cited advantages of MBR systems are reduced footprint compared to the traditional settling tank technology, reduction in excess sludge production, flexible design, automated operation, and improved final quality compared to traditional systems (Brindle and Stephenson, 1996; Howell, Chua, and Arnot, 2004; Le-Clech, Jefferson, and Judd, 2003; Shannon et al., 2008; Wang, Wu, and Tang, 2009a; W. Yang, Cicek, and Ilg, 2006). Due to these strengths, particularly automated operation and small footprint, MBRs may be ideal for decentralized water reuse.

Obstacles to Water Reuse

There are still significant challenges to decentralized water reuse that need to be overcome. When water reuse technologies are installed near to the point of reuse, the travel time from the system to consumer is short. This poses increased risk to the consumer in the event that the water reuse system fails or becomes contaminated (Hambly et al., 2012; Henderson et al., 2009). Large centralized systems can take advantage of the longer travel times from the plant to the consumer, which increases the time for reaction to system failure. Decentralized systems must be able to detect and respond to contamination events much more rapidly than a traditional water treatment system.

In addition to real risk experienced by consumers, there is an added perceived risk toward water reuse systems. Hambly et al. (2012) published a review of cross-connections related to dual reticulation systems, a common use for MBR systems. Included is a review of reported cross connection events between drinking water pipes and recycled water pipes, or cases of contamination of drinking water as a result of failing dual reticulation systems. As a result of these events and the inherent challenge of trusting the quality of recently treated wastewater, the Dutch government has discouraged the use of recycled water in domestic properties and surveys of communities and professionals in the US have shown skepticism toward the quality of reused water (Hambly et al., 2012; Hartley, 2006)

Lastly, in regard specifically to MBR systems, there is the problem of irreversible membrane fouling. It has been reported that this is the primary limitation to the widespread use of MBR systems (Le-Clech, Chen, and Fane, 2006). Membrane fouling contributes to increased pumping costs and decreased flux across membrane surfaces. This leads directly to the necessity of back-flushing and relaxation periods, periods of zero or negative treated effluent production,

as well as frequent cleanings. In response to these drawbacks, the research community has produced a large number of studies on the nature of foulants, and the processes which contribute to their formation (Hur et al., 2014; Kimura et al., 2005; Le-Clech et al., 2006; Maqbool et al., 2016). Currently, soluble microbial products (SMP), or a related organic fraction, extracellular polymeric substances (EPS) are attributed as the largest factor influencing fouling in an MBR. These organic fractions of wastewater bodies are mostly made up of proteins, lipids, and polysaccharides. While there is agreement that these substances are at least partly responsible for fouling, their concentration does not necessarily correlate to fouling rate (Drews, Vocks, Bracklow, Iversen, and Kraume, 2008). Current research is attempting to identify more precisely the foulants themselves and the circumstances that most affect fouling.

Each of these issues present a need for acute, real-time water quality monitoring. Acute, real-time monitoring would allow for more rapid contamination or treatment failure, thereby allowing appropriate action to be taken to protect the consumer. This may also increase public confidence in water reuse systems. Lastly, detailed monitoring throughout the system may increase understanding of how and why membrane fouling occurs and allow for improved MBR operation, thereby decreasing irreversible fouling and associated costs.

Water Treatment Monitoring

Before water reclamation technologies become standard in new developments and projects, public perception of treated water quality and safety, as well as the actual safety of these technologies, must increase. These hurdles can be overcome by rapid, acute, real-time monitoring technologies that reliably detect changes in water quality related to treatment failure or cross contamination.

Studies in this area have been collected in reviews and have covered a broad variety of monitoring techniques (Hambly et al., 2012; Henderson et al., 2009). The techniques evaluated include BOD, COD, TOC, metal ion concentrations pH, free chlorine, oxidation reduction potential, dissolved oxygen (DO), electric conductivity (EC), turbidity, chloride, ammonia, and nitrate. Of these, only EC and TOC have been shown to be able to differentiate between potable and recycled water, but only for extreme values (**Table 2**).

Water quality parameter	Potable water values	Recycled water values
TOC (mg/L)	0.4-6.4	0.1-6.7
EC ($\mu\text{S}/\text{cm}$)	13-570	65-1240

Table 2 - Range of reported water quality parameters from Henderson et al. (2009)

While TOC and EC do vary between potable sources and recycled water sources, there is significant overlap (**Table 2**). The detection limit of these two techniques in this context is around 5% intrusion, meaning 5% of the potable water flow is now recycled water. This is only if the conductivity difference is $700\mu\text{S}/\text{cm}$ or TOC difference is $3\text{mg}/\text{L}$ or more and it is clear that recycled water and potable water can have TOC and EC values that differ much less than this (**Table 2**, Henderson et al., 2009). A superior monitoring technique is desired. Fluorescence spectroscopy has shown much promise in this regard.

Principles of Fluorescence Spectroscopy

The phenomenon of fluorescence is the emission of light caused by an energetically excited molecule relaxing to a ground state (Lakowicz, 1999). Excitation takes place when a molecule's electrons absorb light at a wavelength that corresponds to the difference in energy between the electron's current (likely ground) state and a more excited state (S_1 or S_2 , typically).

The reverse of this absorption process is fluorescence where the excited electron quickly falls back down to the ground state and emits light at the wavelength corresponding to the amount of energy lost by the electron. Between the two processes of absorption and fluorescence, internal conversions are likely to occur. Internal conversion describes the transfer of the excited electron from one energy state to another state at a nearly identical energy level. Generally, excited electrons fall to the lowest vibrational energy level (the lowest S_1 or S_2 level) before falling to the ground state and emitting fluorescence. Since the wavelengths of light both emitted and absorbed are defined by the energy levels of the fluorescing molecule, the fluorescing light offers information as to the chemical nature of the molecule (**Figure 1**, Lakowicz, 1999).

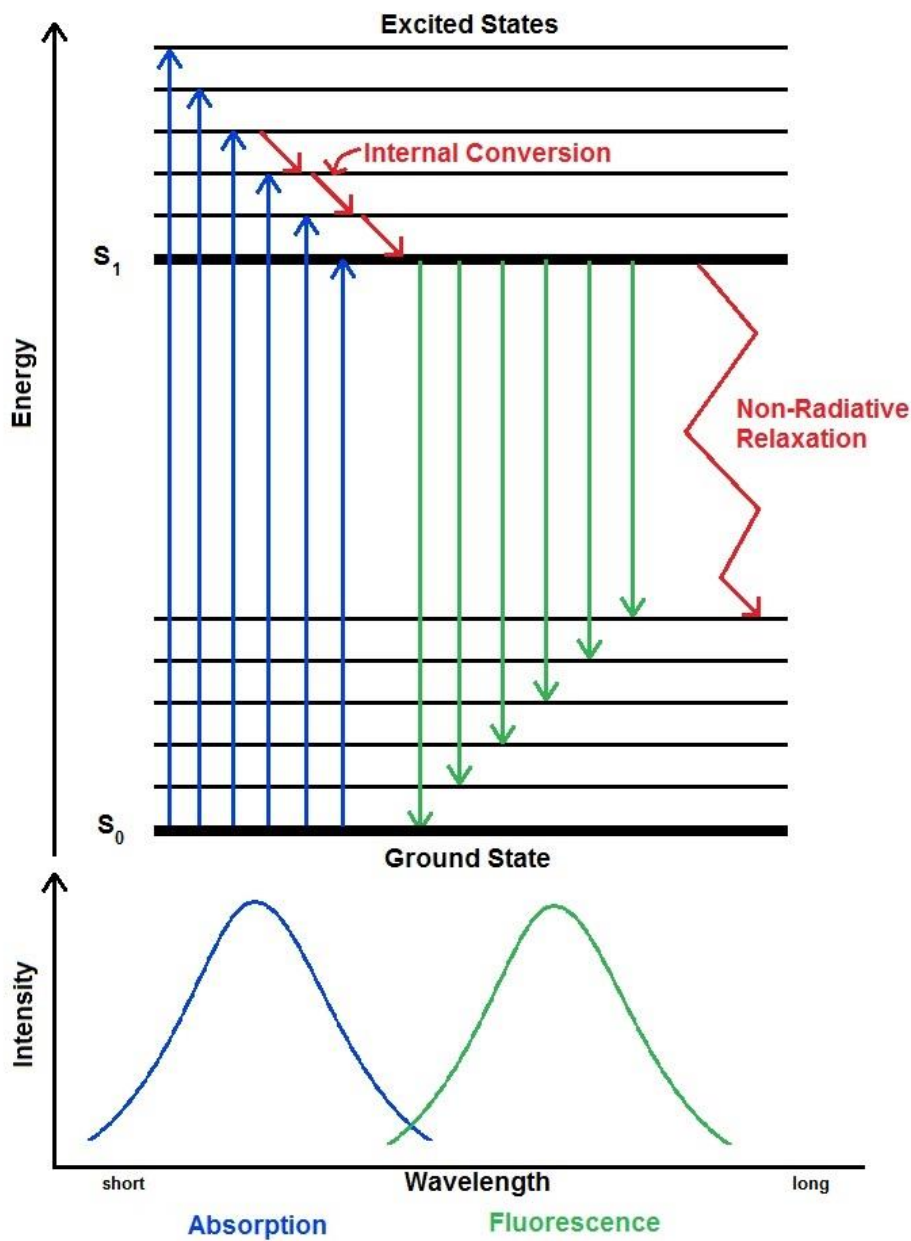

Figure 1 - Jablonski diagram of a fluorescing molecule. (Adapted from Hudson et al., 2007)

The upper portion of **Figure 1** is an illustration of the possible energy transformations initiated by the absorption of light. Once the light is absorbed and an electron is excited, the electron may undergo fluorescence or non-radiative relaxation. Non-radiative relaxation occurs when excess energy is lost due to vibrations.

Due to the rapid and repeatable nature of the energy transformations that result in the release of fluorescent light, the fluorescence technique is extremely sensitive, such that a single fluorescing molecule may be detected (Peck, Stryer, Glazer, and Mathies, 1989). In addition to high sensitivity, fluorescence techniques are highly selective and non-destructive. The selectivity stems from the influence that the structure and functional groups of a molecule have on the wavelengths emitted and absorbed.

Fluorescence Monitoring of WW

Over the past 20 years, fluorescence spectroscopy has been used to characterize aquatic organic matter in natural waterbodies and wastewater streams (Coble, Green, Blough, and Gagosian, 1990; Coble, 1996; Vasel and Praet, 2002). Methods have evolved from taking single peak fluorescence measurements to generating three dimensional matrices from sequential excitation-emission measurements (Stedmon et al., 2003). These three dimensional structures are called excitation emission matrices (EEMs). In addition to the improvement of fluorescence measurements, several analytical methods have been developed to extract more usable information from emission spectra.

A common use for fluorescence spectroscopy is in the analysis of dissolved organic matter (DOM). DOM is a complex mixture of carbon based compounds and are heavily present in wastewater and therefore relevant to the present study. The properties of DOM will be covered in a subsequent section (**Dissolved Organic Matter**).

In regards to DOM, several classes of molecules have been identified from their fluorescent properties or have been shown to have unique fluorescent properties. The fluorescence characteristics of DOM are typically taken by consecutive scans across a range of

emission wavelengths using iterating excitation wavelengths. These scans are collected and used to create an EEM. Based on the composition of the fluorophores present, fluorescence of DOM generally offers information about proteins and humic-like substances present (**Figure 2**)(**Table 3**).

Figure 2 - EEM of MBR effluent from the present study with commonly observed peaks labeled. The scale of fluorescence intensities are in Raman units.

Parameter	Excitation / Emission Wavelengths	Description	Source
Peak B	270-275/304-312	Tyrosine	Coble 1998
Peak T ₁	275/340	Tryptophan	Coble 1996
Peak T ₂	225-237/340-381	Tryptophan	Coble 1996
Peak M	290-325/370-430	Marine/Algae	Coble 1998, Stedmon and Markager 2005
Peak C ₁	320-340/410-430	Fulvic	Baker 2001
Peak C ₂	370-390/460-480	Humic	Baker 2001
Peak A	237-260/400-500	Humic	Coble 1996

Table 3 - Commonly identified fluorescence peaks present in DOM

Studies using 3D fluorescence spectroscopy to analyze DOM initially arose in the field of oceanography (Baker, 2001; Coble et al., 1990; Coble, 1996). These studies largely focused on the character and identity of the fluorophores. Use of this technique then spread to the study of freshwater (Del Castillo et al., 1999; Galapate et al., 1998; McKnight et al., 2001; Spencer, Bolton, and Baker, 2007) and wastewater treatment (Ahmad and Reynolds, 1999; Hambly et al., 2012; Henderson et al., 2009; Hudson, Baker, and Reynolds, 2007; Reynolds and Ahmad, 1997).

From these EEMs, scientists are able to extract much information about the character of the OM in the source water. The presence of a given peak may reveal the presence of the corresponding type of organic matter. Peaks C₁ and C₂ are representative of fulvic and humic-like matter, respectively (Baker et al., 2001). Peak A also corresponds to humic substances (Coble et al., 1996). Peak M is a humic peak originally thought to be associated with marine waters, but has more recently been associated with algae (Coble et al., 1996; Stedmon and

Markager, 2005). Peaks T₁ and T₂ are caused by tryptophan-like substances and Peak B by tyrosine like compounds (Coble et al., 1996).

Correlations to Water Quality Parameters

In addition to each peak describing a group of compounds, peaks also correlate to water quality parameters. Measures of carbon are useful in water treatment systems. These include BOD, COD, and TOC, but each of these traditional parameters has drawbacks for online monitoring. BOD is very time consuming, taking several days, and is imprecise. COD is much quicker than BOD, but still takes hours to measure and uses harmful chemicals. TOC is a technique rapid enough for online monitoring, but, along with COD, cannot differentiate biologically available carbon from biologically inactive carbon (Carstea, Bridgeman, Baker, and Reynolds, 2016).

Some correlations between fluorescence EEMs of various water sources and water quality parameters have been collected in a review by Henderson et al. (2009) (**Table 4**). The strongest correlations have been shown by the protein related peaks T₁, T₂. In sewage works, T₁ has shown strong correlations with BOD ($r = .96$), COD ($r = .97$), and TOC ($r = .96$) (D. Reynolds, 2002). Peaks A and C have been shown to correlate with BOD with a high Pearson's r of 0.77 and 0.72 respectively (Hudson et al., 2008).

Source Water	Peak	Water Quality Paramater	Pearson's r	Reference
river water	T1	PO ₄ ³⁻	0.8	Baker and Inverarity 2004
		NO ₃ ⁻	0.87	
	T2	BOD	0.85	
		NH ₃ ⁻	0.7

Table 4 - Selected correlations between water quality parameters of interest and fluorescence peak intensity (adapted from Henderson et al. 2009)

Effect of Treatment on Fluorescence

From these correlations, it is possible to predict and study the ways in which a given wastewater treatment train will affect the fluorescence peaks of the water. Henderson et al. (2009) composed a table which describes a typical treatment train and the expected effect on DOM fluorescence. **Table 5** shows the treatment train used in a typical MBR and the corresponding effects. From this treatment train, T₁ and T₂ peaks would likely be the most

influenced by the treatment process and therefore hold promise for both monitoring treatment efficiency and breakthrough detection.

Stage	Process	Target constituent	Impact on fluorescence	Reference for correlation between constituent and fluorescence
Raw sewage				
Screening/grit removal	SaniTee filter	Solids, non-degradable matter		
Primary treatment	Settling tank	SS, BOD	T ₁ , T ₂ intensity decrease	Hudson 2008
Secondary treatment	Activated sludge bioreactor	BOD ^a , NH ₃ ^{-a} , COD ^b	T ₁ ^b , T ₂ ^a intensity decrease	Baker and Inverarity 2004 ^a , Reynolds 2002 ^b
Tertiary treatment for nutrient removal	Oxic/anoxic cycling	NO ₃ ⁻ , PO ₄ ³⁻	T ₁ , T ₂ intensity decrease	Baker and Inverarity 2004
Filtration	Membrane microfiltration (0.2µm pore size)	SS, colloids, bacteria	Decrease in all fluorescence intensity	Z. Wang 2009
Disinfection	UV	Bacteria and virus	Decrease in T ₁ intensity, increase in C ₁ and C ₂ . Blue shift of peak locations	Choi and Choi 2010
Recycled water				

Table 5 - Impacts of treatment processes on fluorescence. (Adapted from Henderson et al. 2009)

Simply examining the peaks, however, makes minimal use of the wealth of information present in EEMs. A more detailed analysis can yield useful information and retains the rapid, real-time nature of peak picking methods. Several techniques have been developed to extract more information from EEMs. These methods involve considering the volume under the EEMs

at certain regions, the slopes of peaks, and statistical methods for breaking the large volume of data into its underlying components (**Table 6**).

	Calculation	Description	Source
T ₁ to C ₁ ratio	(em intensity at ex 275 em 350)/(em maximum observed within ex 320-340nm em 410-430nm)	T1:C1 ratio of sewage impacted waters has been shown to be ~1.0, whereas natural waters have a higher ratio ~3.0	Baker 2001
fluorescence index	(em intensity at 450nm) / (em intensity at 500nm) taken at ex 370nm	Ratio has shown differences in microbial (1.9) and terrestrially (1.4) derived organic matters. Method requires isolation of fulvic acids	Mcknight 2001
freshness index	(em intensity at 380nm) / (em maximum observed between 420nm and 435nm) taken at 310nm	Numerator represents more recently derived DOM; denominator more decomposed DOM	Parlanti et al., 2000; Wilson and Xenopoulos 2009
humification index	(area under emission spectra from 435-480nm) / [(area under emission spectra from 435-480nm) + (area under emission spectra from 300-345nm)] taken at ex 254nm	Used for determining the extent of humification (decomposition) of a DOM sample	Ohno 2002
specific UV	(UV absorbance at 254nm) / (DOC concentration in mg/L)	Surrogate parameter for % aromaticity	Weishaar et al. 2003
spectral slope ratio	(slope of 275-295nm region of UV absorbance spectrum) / (slope of 350-400nm region)	Related to DOM molecular weight, photobleaching, and source	Helms et al. 2008
fluorescence regional integration	Integrated volume of five EEM regions normalized for the area integrated and DOC concentration	Used to differentiate wastewater effluent DOM from drinking water DOM	Chen 2003
PCA	A mathematical reduction of the EEM into orthogonal vectors that describe the most variation in the matrix	PCA analysis produces a primarily mathematical description of the variation of the data. This creates difficulties in interpretation, however it has been used successfully in differentiating DOM sources and correlating fluorescence to COD.	Persson andWedborg, 2001; Stedmon et al. 2003; Galinha and Claudia, 2011

PARAFAC	PARAFAC is a multi-way analysis method that breaks the EEM into underlying fluorophores	PARAFAC is similar to PCA in that the data is broken into underlying components, however PARAFAC retains a clear relationship with the chemical components of the mixture	Stedmon et al. 2003
redox index	$(Q_{red})/(Q_{red} + Q_{ox})$	Q_{red} is the sum of all the reduced components identified by PARAFAC and Q_{ox} is the sum of all the oxidized components, giving the oxidation state of chromophoric DOM	Miller et al. 2006

Table 6 – Description of commonly used techniques for analysis of EEMs

Interferences

When properly handled, fluorescence spectroscopy provides a wealth of information, but there are many factors that can create artifacts in the EEMs that are not related to the nature of the DOM being studied. These artifacts include the drift of peak locations and changes in peak intensity and may vary at different excitation and emission wavelengths. Many potential effects have been reviewed by Henderson et al. (2009) and Hambly et al (2012).

The most ubiquitous features in fluorescence EEMs are referred to as Raman and Raleigh-Tyndall effects. The Raman effect appears as a thin line in the EEM across excitation 260-350 nm and emission 280-400 nm (Hudson et al., 2007). This feature is caused by the vibration of the O-H bonds in water molecules caused by incident light and is used as an internal standard to correct for instrument bias in the comparison of collected EEMs across instruments (Hudson et al., 2007). The Raman effect is easily removed from the spectra by subtracting a pure water EEM as a “blank” from the sample EEM. The Raleigh-Tyndall effect is the reflection of the incident light off of the sides of the cuvette (Hudson et al., 2007). These features are located where the excitation and emission wavelengths are equal or where emissions wavelengths are twice that of the excitation wavelengths. These appear as uniform bars cutting across the EEM.

These features are either removed from the spectra by entering null values in the regions where they are present or are simply left in place.

Inner filtering effects (IFE) occur when the excitation or emission light is absorbed by the sample rather than the emission detector, resulting in decreased fluorescence intensity or a distortion of the spectra (Henderson et al., 2009). This effect can take place in two different ways. First order inner filtering occurs when the excitation light is absorbed by the sample prior to the light reaching the interrogation zone; that is, before the light reaches the portion of the sample that the emission detector is reading. Second order inner filtering occurs when the light emitted as fluorescence is reabsorbed by the sample prior to the light leaving the sample and entering the emission detector (Ohno, 2002). This is possible because the light emitted and absorbed in the fluorescence process are often close in wavelength (see **Figure 1**). Both of these effects are prevalent when the samples are at high optical densities. In the case of wastewater treatment, this would mean that the chromophoric DOM are in high concentration. A study by Hudson et al. (2007) showed that treated wastewater samples with TOC values less than 25mg/L showed no IFE. In the case that IFE is present, Ohno (2002) has developed a mathematical correction factor IFE that is commonly used.

Temperature is another variable that is well known to influence fluorescence intensity. In general, as temperature increases 1° C, fluorescence intensity decreases by about 1% (Henderson et al., 2009). This is a result of increased vibrational modes of relaxation compared to photon emitting modes (**Figure 1**). To avoid the effects of temperature on fluorescence measurements, samples need to all be analyzed at the same temperature or a correction factor for the group of samples in question needs to be created and applied. Temperature effects are linear which allows for a correction factor to be created easily, but this correction would have to be performed for

each peak of interest. For example, Baker and Inverarity (2004) show that temperature affects the $T_1:C_1$ ratio, indicating that different regions of the EEM may experience differing temperature effects. Additionally, the correction factor is only possible provided that all samples have a very similar composition. This is often not the case and since EEM variations between samples are often of interest, the best approach is to operate under uniform temperature when possible.

Extremes of pH have been shown to modify fluorescence, and unlike temperature, the effect is nonlinear. Generally the effect of pH on each peak is to increase fluorescence intensity from a pH of ~2 to some higher value and then decrease as pH continued to increase (Henderson et al., 2009), reflecting that each peak in fluorescence has its crest at different pH values. Due to the nonlinear effects of pH on fluorescence EEMs, in situations where pH is very high or very low and variable, samples should all be analyzed at a uniform pH. In the context of sewage treatment, pH effects are generally negligible due to the low variability within a treatment system (Hambly et al., 2012).

Fluorescence has been shown to be affected by metal ions in solution as well. The effects of the ions vary by species and by the character of the DOM. McIntyre and Guéguen (2013) analyzed a number of common metal ions via titration of the ions into algae derived DOM and stock DOM samples. While their experiment showed that metal ions have an impact on fluorescence EEMs, little work has been done investigating the presence and state of metals in the context of recycled water systems (Henderson et al., 2009). It is generally considered that metals in the environment are present in colloidal form or complexes. These types of metal species have not been shown to affect fluorescence, however some studies correct for metal ion effect by reducing pH to 2, in order to precipitate the metals out. This, then, introduces pH

effects and changes the fluorescence signal which must be taken into account when relating data collected in this way with data from other sources.

Chlorine and ozone are chemicals commonly used for disinfection purposes in wastewater treatment. These chemical species disinfect by breaking chemical bonds and inserting oxygen or chlorine species. This affects the chemical nature of DOM in a water sample (Swietlik and Sikorska, 2004), and, in turn, affects the fluorescence of that sample. Specifically, oxidation can shift peak locations to either higher or lower wavelengths as well as increase some peaks' intensity and decrease others' (Liu et al., 2011; Swietlik and Sikorska, 2004). Different types of oxidants can also induce different shifts in peaks. Swietlik and Sikorska observed that oxidation by ozone shifted EEM peak locations toward longer wavelengths (red-shift), while oxidation via chlorine dioxide shifted peaks toward shorter wavelengths (blue-shift) (Liu et al., 2011; Swietlik and Sikorska, 2004). Along with chemical methods of oxidation, UV light has been shown to oxidize compounds, and is often used in disinfection of treated sewage (Choi and Choi, 2010). Due to the complexity of these effects, in order to avoid them wastewater effluent samples may be collected prior to oxidation.

PARAFAC

Once interferences have been accounted for, there are a variety of powerful analytical methods available for extracting data from EEMs. One of the most widely used is PARAFAC, or parallel factor analysis. It is a multivariate analysis technique that, when applied to EEMs of DOM, is able to mathematically separate the underlying fluorophores that make up the dataset (Stedmon et al., 2003). These underlying fluorophores are called components. PARAFAC has the unique advantage over similar techniques in that the components identified in a validated

model relate to chemically identifiable fluorophores (Stedmon et al., 2003), such as humic-like or tryptophan-like material.

PARAFAC of a 3D dataset decomposes the data into a set of trilinear terms and a residual matrix (Murphy, Stedmon, Graeber, and Bro, 2013):

$$x_{ijk} = \sum_{f=1}^F a_{if} b_{jf} c_{kf} + e_{ijk}$$

where $i = 1, \dots, I; j = 1, \dots, J; k = 1, \dots, K$. When applied to a set of EEMs, x_{ijk} is the point in the dataset corresponding to the i^{th} sample, j^{th} emission wavelength, and k^{th} excitation wavelength (**Figure 3**). There are I samples in the dataset, K excitation wavelengths, and J emission wavelengths.

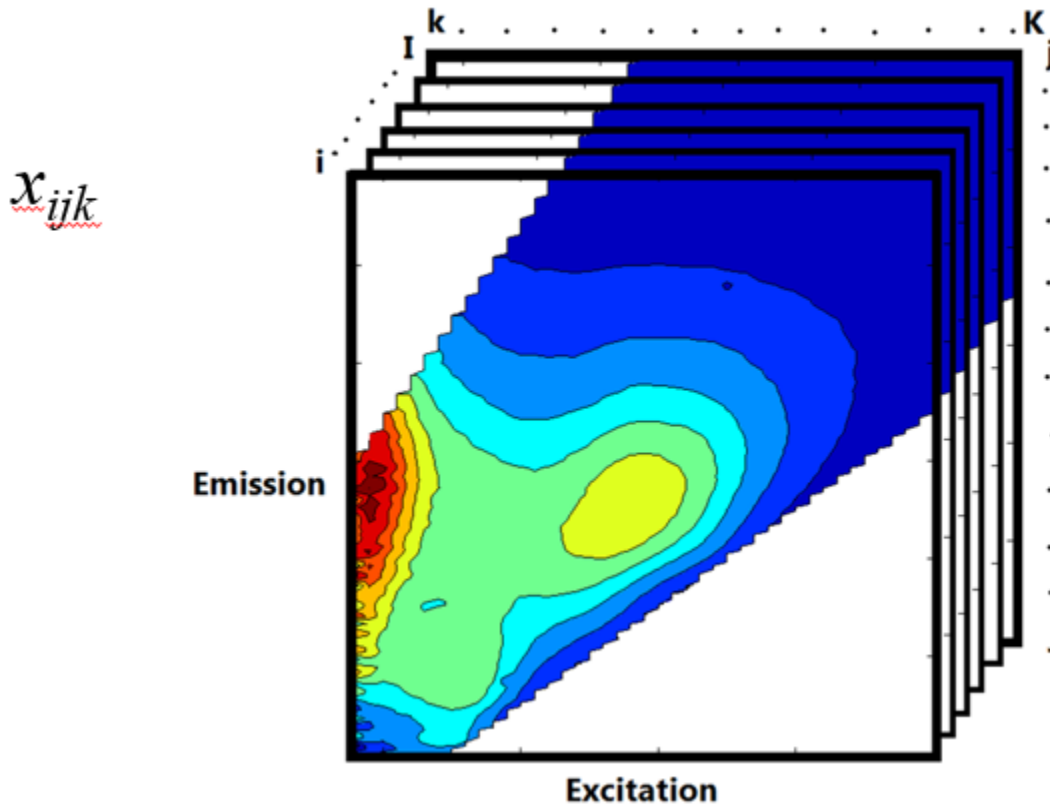

Figure 3 - Diagram of a dataset of EEMs arranged in a 3D structure. EEM shown is from the present study. (Adapted from Murphy et al., 2013)

Each f in the above equation corresponds to one of F PARAFAC components in the model. Each component has an estimated value for each location in the three dimensional dataset. That is, each component has I a values, one for each sample, J b values, one for each emission wavelength, and K c values, one for each excitation wavelength. The unique benefit of PARAFAC is that the created components reflect fluorescence spectra of an identifiable group of chemical compounds. As a result of this attribute of valid PARAFAC components, a , b , and c values correspond to real physical attributes of the fluorophores present. These parameters correspond to the concentration, emission spectrum, and molar absorptivity of the f^{th} fluorophore, respectively. The remaining e_{ijk} is a matrix containing the error between the sum of the estimated components and the point being estimated.

Limitations of PARAFAC

Studies have also been performed on the PARAFAC method itself, aiming to answer questions about the sensitivity, repeatability, or potential weaknesses of the method. A recent paper on this subject was published by Yu et al. (2015).

Yu et al. (2015) collected samples from diverse sources to investigate the sensitivity of PARAFAC to diverse sources of DOM. Samples were collected from an oligotrophic river (n=76), WWTP effluent (n=62), and extracellular organic matter from *Microcystis aeruginosa* (n=85). Yu et al. (2015) demonstrated that similar, but overlapping spectral components in samples can inhibit the ability of the PARAFAC model to differentiate between spectral components. Even if this occurs only at in a single component, the estimation of PARAFAC components happens simultaneously and the erroneous estimation of one peak can influence the

estimation of others as well. For this reason, Yu et al. (2015) stated that PARAFAC can only be effective in contamination warning and online monitoring when there is no overlap in components.

A potential solution to this problem is to use the peak-picking method instead. Murphy et al. (2011) has shown that PARAFAC components correlate strongly to selected peak wavelengths. This method avoids the noise created by shifts in peak / component locations and can therefore register the signal rather than noise.

Due to the data intensive and time consuming nature of PARAFAC, its strengths and limitations should be considered before using this method. However, if used in the proper context, this methods has the potential to provide detailed information about the underlying fluorophores present in a set of EEMs and thereby information on the types of carbon species present in a sample (Stedmon et al., 2003).

Dissolved Organic Matter

In the context of municipal wastewater reuse, dissolved organic matter (DOM) is of concern because it contains trace levels of personal care products and pharmaceuticals, and reacts with disinfectants to produce potentially carcinogenic byproducts. DOM has been the subject of much research for the past 100 years (Williamson, Morris, Pace, and Olson, 1999). These studies have investigated the composition, concentration, cycling, ecological role, role in water treatment processes, membrane fouling properties, and myriad other characteristics of DOM and in a variety of environments. The treatment of DOM in this research has often been either chemical or in regard to its ecological role.

In terms of chemical characteristics, DOM is composed of large heterogeneous hydrocarbon molecules ranging from 100-100,000 Da (Da being Daltons, a measure of atomic mass), which is in the colloidal size range (Leenheer and Croue, 2003). These compounds are formed, in part, from lower molecular weight compounds through humification, which takes place largely from microbial synthesis (Sparks, 1995). These molecules can have amide, carboxyl, hydroxyl, ketone, and other functional groups (Baker, Tipping, Thacker, and Gondar, 2008; Leenheer and Croue, 2003). In addition, DOM varies as it moves away from its source as predominately biological processes degrade the material for energy (Stedmon et al., 2003). Due to the breadth of this definition, it is not particularly descriptive, but due to the complexity of the mixture of constituents and of the variability of DOM in space and time, the breadth is necessary. The chemical makeup of DOM determines its optical properties. This optically active portion of DOM is referred to as chromophoric dissolved organic matter (CDOM) and is related to the large number of aromatic hydrocarbon rings found in DOM. Although less than 1% of DOM moieties are fluorescent, nearly all natural waters exhibit fluorescent character. Due to the ubiquity of CDOM, UV absorbance and fluorescence spectroscopy are often used to characterize DOM in water samples and can be correlated to other chemical properties such as TOC, COD, BOD, $[\text{PO}_4^{3-}]$, $[\text{NO}_3^-]$, $[\text{NH}_3]$, $[\text{NH}_4\text{—N}]$ (Henderson et al., 2009). Apart from correlations to other water quality parameters, fluorescence spectroscopy can reveal information about the types and source of organic matter present. This will be covered in detail later in this paper.

In a natural environment, allochthonous DOM is a result of the degradation of terrestrial plant material and soil humic substances from the associated watershed. Therefore, factors such as land use, canopy cover, and river order impact allochthonous DOM in terrestrial waters. This material consists of less reactive and more colored humic and fulvic acids (Wetzel, 1983). The

remaining fraction of DOM is autochthonous and is a result of the excretion of phytoplankton or macrophages (Wetzel, 1983). Ecologically, DOM fulfills a variety of roles including contributing to the transport of organic and inorganic contaminants, influencing transport of metal ions, providing carbon for biological processes, mediating photochemical processes, and attenuating light in natural waters (McIntyre and Guéguen, 2013; Mopper and Kieber, 2002; Tessier and Turner, 1996; Walsh et al., 2003). Due to the importance of these ecological roles, the character and concentration of DOM in a given environment has implications for that system's ecosystem services. While DOM has been shown to increase coagulation and sedimentation rates of heavy metal ions in lake and river ecosystems (Wilkinson, Joz-Roland, and Buffle, 1997), an increase in DOM is generally considered to have negative effects on an ecosystem. An experiment by Christensen et al. (1996) using a split-lake design has shown an increase in DOM can cause increasing water color, decreasing 1% attenuation depth of photosynthetically active radiation, decreasing maximum depth of oxygenation, and increasing the proportion of the phytoplankton community in the epilimnion as compared to the reference basin (Williamson et al., 1999). These negative effects are associated with the process of eutrophication and are symptoms of decreased water quality.

Anthropogenic DOM that enters the environment is mainly related to treated wastewater. This treated wastewater is characterized by large nutrient and pathogen loads. In many wastewater treatment schemes a combination of biological digestion and settling are used to remove organic matter. However, more recent technologies have also proven successful at DOM removal. The membrane bioreactor (MBR) is a semi recent technology that is currently the attention of much research (Brindle and Stephenson, 1996; Hur, Shin, Kang, and Cho, 2014; Judd and Judd, 2006; Kimura, Yamato, Yamamura, and Watanabe, 2005; Liu, Chen, Yu, and

You, 2011; Ma et al., 2013; Maqbool, Quang, Cho, and Hur, 2016; Meng et al., 2009; Zhang, Chua, Zhou, and Fane, 2006).

Treatment Monitoring

Fluorescence spectroscopy often correlates well with traditional water quality parameters and can therefore be used as a surrogate parameter for some time consuming tests such as BOD or COD (**Table 4**, Henderson et al., 2009). However, fluorescence is most valuable in its ability to provide insight into the types of carbon present throughout water treatment trains, where other carbon measurements cannot (Henderson et al., 2009). This benefit has been well researched and, recently, PARAFAC has been included in this type of study (Baker and Inverarity, 2004; Shutova et al., 2014; Stedmon et al., 2011). For example, it has been found that physical treatment processes and biological treatment processes preferentially remove humic substances and protein-like substances, respectively (Baghoth et al., 2011; Cohen et al., 2014; Yang et al., 2014). This information has led to the effective monitoring of treatment via the tryptophan-like component (Baghoth et al., 2011; Cohen et al., 2014; Stedmon et al., 2011; Yang et al., 2014).

There have been limited attempts to use fluorescence to investigate changes in MBR water quality over time, all of which were at benchtop or pilot scale (Hur et al., 2014; Maqbool et al., 2016; Zhou et al., 2012). In each case, the fluorescence character of the effluent changed minimally over time, while changes from within the reactor were more obvious. These changes over time reflected a cake layer formation on the membrane surface, thus dividing the membrane system performance into two periods, cake layer formation and post formation (Hur et al., 2014; Maqbool et al., 2016).

While these studies offer guidance, additional research has shown that lab scale experiments mostly offer qualitative information in regards to operation of full scale MBR systems (Kraume et al., 2009). Research suggested this was due to differences in hydrodynamic conditions, sludge freshness and composition, ambient conditions, and energy input (Kraume et al., 2009). There is need for investigation of fluorescence based treatment monitoring of a full scale MBR system.

Fluorescence and treatability

As a type of treatment monitoring, fluorescence has been used shown to correlate to DOC removal by different common treatment processes and in different environments (Baghouth et al., 2011; Hur and Cho, 2012; Shutova et al., 2014), and to biodegradability (Yang et al., 2014). So far, this has been done effectively by creating regressions with ratios of, or combinations of humic and protein like PARAFAC components (Shutova et al., 2014; Yang et al., 2014).

The ability to determine treatment efficacy in terms of a bulk carbon measurement prior to installing new water treatment infrastructure is a valuable tool in cost assessment and in determining the treatment steps necessary to achieve the desired water quality. Organic matter poses several problems to efficient treatment of wastewater causing membrane fouling, oxidant demand, disinfection byproduct formation, and poor coagulation efficiency (Ishii and Boyer, 2012; Wang et al., 2009a; Yang et al., 2014).

These studies on treatability indicate that PARAFAC can elucidate the treatability of DOM in both DW and WW treatment plants. The present study aims to improve the correlations found between the influent DOM and effluent quality. As Yang (2014) supposed, the inclusion of more water quality parameters into these regressions may improve our ability to predict the

treatment methods best suited for DOM removal and predict effluent water quality. This study aims to determine a fluorescence based parameter that shows good correlation to TOC removal.

Contamination Detection

By the same principles that allow fluorescence to be effective at monitoring treatment efficacy, fluorescence spectroscopy also has the potential to be an effective monitoring technique for contamination detection. This is also an area of research yet to be well explored. Two studies have been done to determine the detection limit of wastewater contamination in drinking water.

Stedmon et al. (2011) simulated wastewater contamination of a groundwater supplied drinking water system by creating a series of dilutions from a single wastewater sample from a nearby wastewater treatment plant. The detection limit was determined by changes in a fluorescence ratio that corresponded to the tryptophan-like peak intensity over some low-noise background region. The detection limit corresponded to this ratio exceeding two standard deviations of the drinking water fluorescence ratio. (Hambly et al., 2010) performed a Monte Carlo Simulation to determine the contamination detection limit of non-potable recycled water in drinking water. This study used purely statistical methods to determine the detection limits of fluorescence monitoring. The detection limits determined were very different, as were the applied methods. Therefore is room to investigate the detection limits of fluorescence techniques using different source water and treatment levels, and of different water treatment systems. Additionally, both studies leave room for improvement in their methods. The present study aims to build upon this body of work by determining detection limits of a water reclamation system designed for non-potable reuse and by using multiple pairs of corresponding samples from the

oxic tank and effluent rather than one pair of samples to take into account the variability of wastewater and treated effluent of an MBR system.

Research Objectives

Research in wastewater treatment monitoring has largely focused on improving the monitoring of WW treatment in order to optimize the process. This has been done by correlating fluorescence to other wastewater quality parameters (Baker, 2002; Baker and Inverarity, 2004; Baker et al., 2008; D. M. Reynolds, 2002; Vasel and Praet, 2002) and more recently, using PARAFAC to inform the selection of wavelengths for online monitoring, followed often by correlations to water quality parameters (Baghoth et al., 2011; Cohen et al., 2014; Hur et al., 2012; Shutova et al., 2014; Stedmon et al., 2011; Yang et al., 2014). This was beneficial in order to capture the inexpensive and rapid nature of fluorescence spectroscopy as compared to other commonly used water quality monitoring techniques. These studies often focus on WW from a variety of sources and rarely include advanced treatment techniques. There is a need for studies using the PARAFAC method on MBR systems at larger scale, that treat non-synthetic WW to examine if the correlations found in the lab reflect what occurs in realistic treatment scenarios (Kraume, Wedi, Schaller, Iversen, and Drews, 2009).

In response to the need for improved water treatment monitoring, the goals of this study are to: evaluate the effectiveness of fluorescence based techniques to: monitor wastewater treatment throughout a full scale membrane bioreactor, and determine the contamination detection limit of fluorescence techniques in a non-potable reuse scenario.

Chapter 3 - Materials and Methods

Study Site Description

Research was conducted on a full scale membrane bioreactor located in Fort Riley, KS. The MBR was custom designed by Biomicrobics (Lenexa, KS) for the study as part of the Department of Defense Net Zero Water Research initiative (US Environmental Protection Agency, 2016). The MBR design flow was 15000 L/day with a retention time of 29 hrs.

The system contains three tanks: a 2300L settling tank, 7900L anoxic tank, and a 7900L oxic tank providing a total capacity of 18,100L. There were six 0.2 μ m membrane filter stacks submerged in the oxic tank. Each stack was comprised of two cassettes with 7m² of filtration area per cassette, providing 84m² total filtration area (**Figure 4**). The membranes are constructed from a combination of Polyvinylidene Fluoride (PVDF) and Polyethersulfone (PES) and have nominal pore size of 0.2 μ m (Bio-Microbics, 2016). Water was added to the system from a wastewater line servicing multiple military barracks and motor pools. After the diversion from this main line, a grinder pump was installed to reduce clogging in the MBR due to larger debris entering the system.

The effluent pump and blower pump were triggered by a system of float switches in the oxic tank and a timed control. The blower pump was always run when the effluent pump activated to reduce fouling on the membrane surface by maintaining crossflow while the system was operating, but the blower pump also ran for 30min after every 90min of rest time. When the total water level was sufficiently above the top of the stacks, the pumps turn on according to a schedule that provides the designed outflow of 1500L/day. As a safety, when the water level in the system is too high, activating the second float switch, the pumps run regardless of the

schedule until the water level dropped back to normal ranges. If the water level fell too low, the effluent pump would not activate. While the system is in filtration mode (effluent pump is on), the effluent pump ran in 30min cycles with 5 minutes of rest time. The rest time during filtration allowed for the blower pump to scour the surface of the membranes with pressurized surface air and remove particulates that decrease flow rate and increase transmembrane pressure.

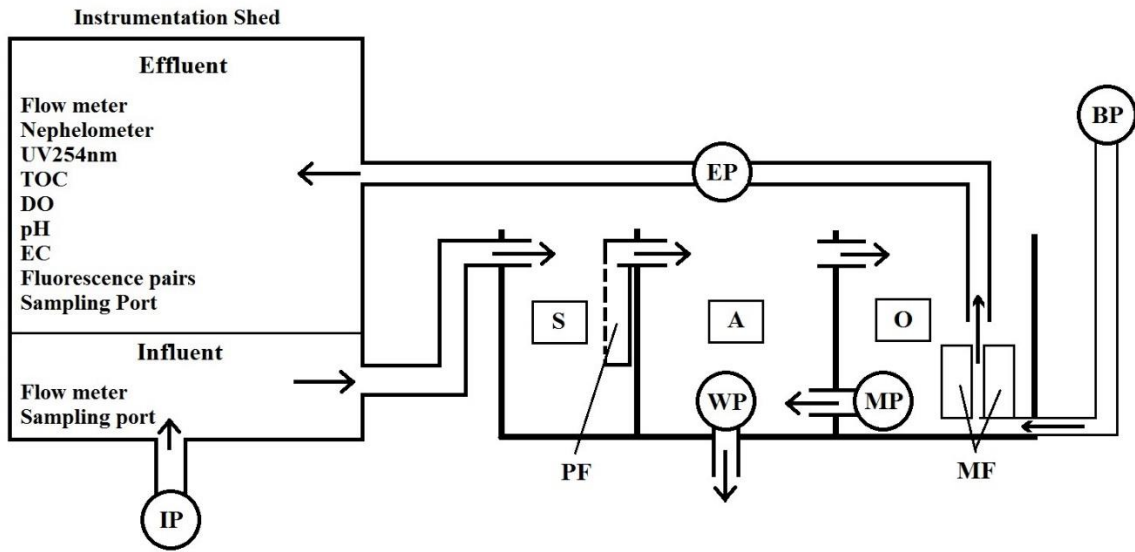

Figure 4 - Diagram of the MBR system. IP - influent pump, EP - effluent pump, WP - waste pump, MP - mixing pump, BP - blower pump supplying oxygen, S - settling tank, A - anoxic tank, O - oxic tank, PF - particulate filter, MF - membrane filter stacks

Instrumentation

The influent and effluent lines of the MBR system were piped through a shed where several continuous water quality monitoring instruments were installed. In the influent line, a 1720E Low Range Turbidimeter (Catalog #6010018, Hach, Loveland, CO), and a Toshiba LF654 Flowmeter (Houston, TX) was installed, which measured flowrate and cumulative flow. The effluent line contained the same flowmeter, a FT660 sc Laser Nephelometer (Catalog

#6016000, Hach, Loveland, CO), a Sievers 5310C Laboratory Total Organic Carbon Analyzer (GE Analytical Instruments, Boulder, CO), a Real UV254 M3000 (Real Tech Inc., Whitby, ON, Canada) which measured absorbance at 254nm, three Campbell Scientific probes including CS547A Conductivity and Temperature Probe, CS511-L Dissolved Oxygen Probe, CSIM11 pH Probe (Logan, UT), and a Turner Designs C6 Multi-Sensor Platform equipped with tryptophan and CDOM fluorescence probes (Part #998-2205, Sunnyvale, CA) which measured fluorescence at excitation/emission wavelengths of 325/470nm and 285/350nm respectively. Both the 1720E and FT660 turbidity instruments were connected to a sc200 Universal Controller Configurator (Catalog #LXV404.99.00552, Hach, Loveland, CO) to supply power and provide maintenance messages from the instruments. Data were collected from these instruments using a Campbell Scientific CR1000 Measurement and Control System with an attached AM16/32 Relay Multiplexer (Logan, UT).

Sample collection

Sampling trips to the MBR system were taken once or twice a week from May to August 2016. On each trip, three 300mL samples were collected from each of three sources: the influent line, the effluent line, and the oxic tank. Additionally, each week a 0.2 μ m Rexeed-25S ultrafilter (Asahi Kasei medical Group, Japan) was used to filter 50L of effluent and an additional 1L influent sample was collected. The ultrafilter and 1L influent sample were sent on ice overnight to the Environmental Protection Agency's National Environmental Research Labs in Cincinnati, OH, for bacteriological analysis. The grab samples were collected in 240mL glass bottles (Catalog # 02991346, Qorpack, Chicago, IL) and stored at 4°C until analysis. Samples were generally analyzed within a week, depending on the test being performed (U. S. Environmental

Protection Agency, 1983). A portion of each grab sample was filtered using 0.45µm sterile filter (Catalog # HAWG047S3, Millipore, Billerica, MA) and separated into two 40mL subsamples. One subsample was acidified with 2% (v/v) 5M HCl (U. S. Environmental Protection Agency, 1983) to pause bacterial action on organic matter for TOC analysis and the other was left at the original pH to minimize the variation in fluorescence characteristics between sample collection and analysis. The remaining unfiltered portion of each grab sample was tested for COD and coliforms and sent to the KSU Soil Testing Labs for chemical analysis.

Chemical and Bacteriological Analysis

Grab samples were analyzed for chemical oxygen demand (COD) directly upon arrival at the laboratory to ensure reliability of the tests. COD testing was done according to the USEPA approved Reactor Digestion Method, Method 8000 described by (Jirka and Carter, 1975) using Hach Low-Range Digestion Solution for COD test kits (Product #2125815, Hach, Loveland, CO), DRB200 reaction block (#LTV082.53.40001, Hach, Loveland, CO), and DR/2400 portable spectrophotometer (#5940000, Hach, Loveland, CO). Effluent samples produced COD values in the detectable range (3-150mg/L COD) for the test kits without adjustment.

Initial influent samples were run at 1/10, 1/5, 1/2, and full concentration to determine the range of values produced for the given dilutions. It was determined that a 1/5 dilution routinely produced values within the detectable concentrations of the COD test kits, the other dilutions of influent were no longer run.

A filtered, acidified subsample was created from each grab sample. Upon analysis, each sample was transferred to clean glass TOC vial that had been acid washed and cooked in a muffle furnace at 550°C for two hours. The samples were loaded into a TOC-L Total Organic

Carbon Analyzer (Shimadzu, Kyoto, Kyoto Prefecture, Japan) and analyzed in triplicate. The closest two samples were averaged for the final result (standard protocol for the instrument).

Nitrogen analysis was completed by the KSU Soils Testing Lab. Samples were collected and sent to them in bulk for chemical analysis. Nitrogen analysis included total, nitrate, and ammonia. Total N was found using a cadmium reduction method according to Hosomi and Sudu (Hosomi and Sudu, 1986). Ammonia and nitrate were found using an Alpkem autoanalyzer according to Alpkem Corp. RFA Methodology no. A303-S021 and RFA Methodology no. A303-170, respectively (Alpkem Corporation, 1986). Influent samples were analyzed for total N and effluent samples were analyzed for total N, nitrate, and ammonia.

Kansas State Soils Testing Lab completed all phosphorus analysis. Total P was measured according to Hosomi and Sudu (Hosomi and Sudu, 1986). Ortho-Phosphate was measured using an Alpkem RFA autoanalyzer according to RFA Methodology no. A303-S200-13 (Alpkem Corporation, 1979). This procedure is an ammonium molybdate blue colorimetric procedure. Influent was analyzed for total P and effluent for total P and ortho-phosphate.

Escherichia Coli and Total Coliforms were analyzed from grab samples on arrival to the laboratory using the Colilert – 18/Quanti-Tray2000 water analysis system. This analysis was done according to IDEXX's IDX 33/02 – 06/12 and IDX 33/01 – 11/09 WATER ANALYSIS METHODS (Dichter, 2011). One Hundred Twenty milliliter shrink-banded vessels with sodium thiosulfate (#98-09221-00, IDEXX, Westbrook, ME) were filled with 100mL sample. Colilert-18 digestion medium (#98-27164-00, IDEXX, Westbrook, ME) was added to the sample and was shaken vigorously until dissolved. The sample and digestion medium were added to Quanti-Tray / 2000 quantification trays (98-21675-00, IDEXX, Westbrook, ME) and sealed in a Quanti-Tray

sealer with rubber 97 well insert (98-9011779-00, IDEXX, Westbrook, ME). The trays were then incubated at 35°C for 18-22hrs and the MPN was recorded from an IDEXX reference sheet.

Fluorescence

A C6 Multisensor platform (Part # 998-2205, Turner Designs, San Jose, CA) was equipped with two Cyclops 7 submersible fluorescence sensors (Part # 998-2100, Turner Designs, San Jose, CA). One fluorometer measured chromophoric dissolved organic matter (CDOM) using excitation/emission wavelengths of 325/470nm. The other fluorometer was used to monitor tryptophan at 285/350nm. The instruments recorded relative fluorescence units (RFU) every 15 seconds at the chosen wavelengths. These fluorescence units were relative values in that they were not compared to a standard, however they were blank subtracted by subtracting the relative fluorescence of deionized water.

Grab samples were stored at 4° C in glass vials in the dark until analysis. Samples were filtered using 0.45µm filter disks. Excitation emission matrices (EEMs) were created using a Jobin Yvon Aqualog Fluorometer (Horiba, Japan) from ex 500nm-240nm with 3nm increments and em 621.49nm-211.76nm with 3.21nm increments (instrument default). Gain was set to high. It was determined that 0.5 seconds was a suitable integration time for most samples, with a few exceptions. The raw EEMs were corrected for inner filter effect (Ohno, 2002), first and second order Raleigh scattering bands removed (Stedmon and Bro, 2008), Raman normalized using 18.3MΩ ultra-pure water at 350nm, and blank subtracted. Additionally, a quinine sulfate standard was run. From the processed EEMs, several indices were calculated. These include: fluorescence index, freshness index, humification index, spectral slope, peak intensities, CDOM, and tryptophan as measured by the Cyclops 7 online fluorometers.

PARAFAC Modeling

PARAFAC is a multivariate analysis technique that is able to mathematically separate the underlying fluorophores present in a set of EEMs (Stedmon et al., 2003). PARAFAC modelling was primarily carried out using the DOMFluor toolbox for MATLAB (REF). The drEEM toolbox (REF) was also used to calculate core consistencies and to project finished models onto larger datasets. The tutorial by (Stedmon and Bro, 2008) was followed in order to create the models. Additional guidance for model selection was found in (Murphy et al., 2013).

Creation of the Total Model

There were $n = 227$ samples collected from the three locations along the MBR treatment train. After the removal of outliers, 198 samples were used for model generation. **Figure 5** is a typical EEM from this dataset with common peak locations labelled. Descriptions of these peaks have been covered previously and are summarized in **Table 3**.

Figure 5 - Typical EEM taken from the dataset with common peak locations labelled.

Preliminary PARAFAC models were created using all samples to determine the approximate number of models necessary to capture the variance of the data and to determine potential outliers. Loadings across all wavelengths and leverages of each sample were calculated from preliminary models in order to identify potential outliers. EEMs were also visually inspected for potential instrument error or other extreme effects that could interfere with the PARAFAC modelling. During this exploratory analysis, several groups of outlier were identified based on the following characteristics (some samples appear in multiple groups):

- a very intense peak at (ex250/em350) (n=11)
- a protein peak at unusually low ex wavelengths (n=7)
- a protein peak with unusually high em wavelengths (n=13)
- a large band at em 550nm (n=6)
- instrument error (n=2)

Samples containing apparent instrument error, the large excitation band at em 500nm, and the low excitation protein peak were removed from the dataset. From this dataset 3, 4, 5 and 6 component models were split half validated according to (Stedmon and Bro, 2008). **Table 7** shows a summary of the the diagnostic information used to choose between the validated models.

The DOMFluor toolbox was used to split the data into 4 different halves. PARAFAC models were created for each half of the data containing 3 to 8 components. Each model was compared to the models created from the other half of the data. If the components identified in both models were sufficiently similar (Tucker correlation coefficients >0.95) the model was validated (Murphy et al., 2013) using Tucker congruence for factor comparison outlined in (Lorenzo-Seva and Berge, 2006).

# of Components	Split Half Validated	Random Initialization Analysis SSE	Core Consistency %
3	Yes	1224.2	74.19
4	Yes	723.4	23.55
5	Yes	372.5	9.32
6	Yes	303.1	2.53

Table 7- Summary of diagnostics used to determine appropriate number of components

Random Initialization Analysis was then run on the models because the initial sample used to create the model influences the outcome. This analysis increased the possibility of finding the universal minimum SSE for the model, rather than a local minimum. This is a common analysis for iterative fitting procedures such as PARAFAC (Stedmon and Bro, 2008).

When the SSE of the replicate models are not reasonably consistent it is a sign that the model is not stable. It may have too many components or need to be re-run with a tighter convergence criteria (Murphy et al., 2013). For this set of models, there was a large reduction in SSE between the 3 and 4 component models and the 4 and 5 component models, indicating an improved fit. The 6 component model showed variable SSE values indicating that the model is unstable.

The core consistency of the models were also evaluated. In a valid model presented by this metric, the core percent returned would be greater than 90%. This positive result would indicate that the components of the model “primarily reflect trilinear variation in the data” (Bro and Kiers, 2003). That is, that the components reflect the variation in the data in the ex, em, and fluorescence intensity directions of the EEM dataset. Models with low core consistency are possibly over fitted and the components are beginning to describe noise as well as variation caused by peaks in the EEMs. As shown in **Table 7**, the core consistency of all the models are low. Recently, (Murphy et al., 2013) has commented that core consistency typically gives larger datasets poor core consistencies. This is potentially due to the fact that larger organic carbon derived models contain covarying components (Murphy et al., 2013).

According to Murphy et al. (2013), adjacent peaks and troughs in the residuals of the modelled EEMs indicate that a single peak is being modelled by two or more components. Alternatively, it could be that a single component is trying to fit two or more narrow peaks. The

residuals from the 4 and 5 component models were investigated for this effect. The peak and trough trend was still present in the 5 component model, as shown in **Figure 6**, but was reduced relative to the 4 component model.

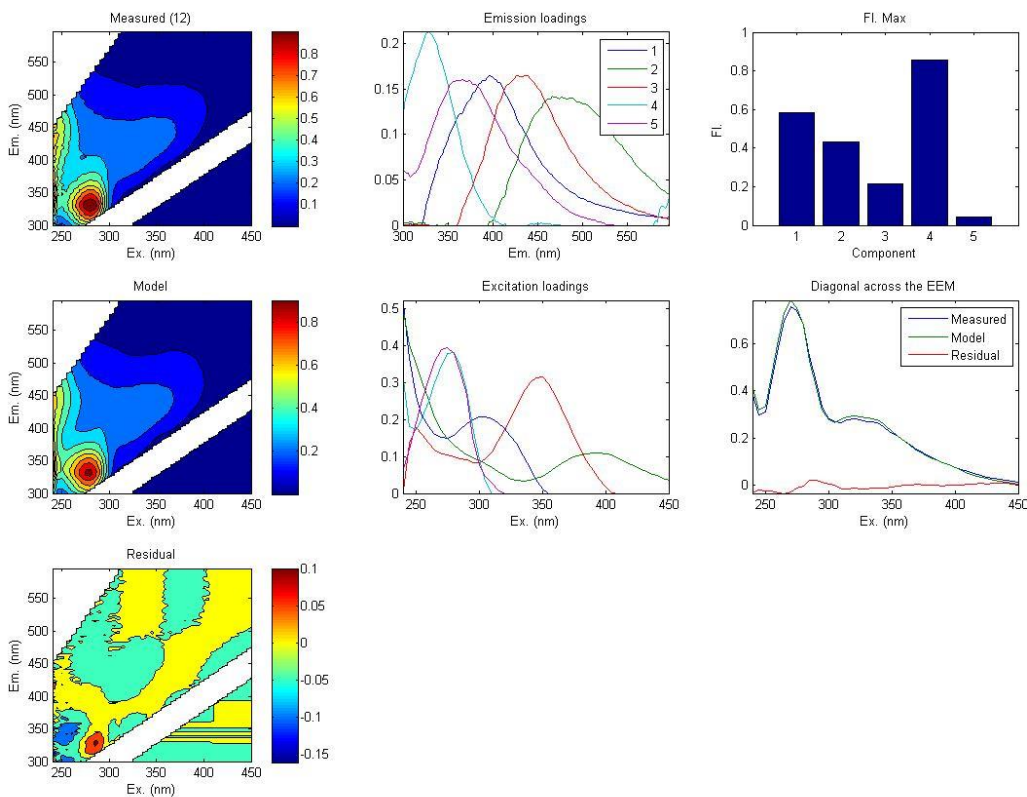

Figure 6 - Mean, modelled, residual plot of a sample in the 5 component model. Adjacent peak and trough is present in the residual plot in the lower left. The z axis of the residual plot is on a smaller scale than the measured and modelled EEMs. The residual peak shown is around 10% of the fluorescence peak in that region.

Apart from the peak and trough, the remainder of the residual EEM showed very little difference between the measured EEM and the model. It is desired that the residual EEMs show very little structure and are made up almost entirely of noise. The residuals were examined and this was the case with the 5 and 6 component models.

Given the above considerations, the 5 component model appeared to be the most appropriate. There was large improvement from the SSE of the 4 component model to the 5 component model. The peak/trough trend that was present in relatively poorly fit EEMs by the 4 component model was reduced by the 5 component model. The 6 component model appeared unstable given the large fluctuations in the SSE from the random initialization analysis and the improvement in SSE from the 5 component model was minimal.

Finally, the spectral loadings of the 5 component model were evaluated for atypical features (**Figure 7**). This inspection was carried out to determine if the components exhibited typical spectral shapes of real fluorophores. A fluorophore should exhibit the following characteristics (Murphy et al., 2013):

1. Minimal overlap between excitation and emission spectra
2. Excitation spectra may have multiple peaks, but emission spectra has one distinct peak
3. When Ex spectra has more than one absorption peak, some absorption occurs between these bands (the spectral loading does not reach zero in between the excitation peaks of the same component)
4. Excitation and emission spectra do not exhibit abrupt changes, but rather gradual changes

Figure 7 - Spectral Loadings of the 5 component PARAFAC model.

The desired criteria are approximately met. Component 2 shows more overlap than the other components, but this effect is still minimal. Components 3 and 5 exhibit abrupt changes in the loadings, but the sharp peaks are not large.

The components identified by the 5 component model exhibit characteristics of real fluorophores and do not show reason for rejecting the model. The outputs of the 5 component model were used for analysis.

Effluent Model

A second dataset was created from effluent EEMs. These EEMs generally contained larger humic peaks relative to protein peaks. The Effluent Model was created using the same process as the Total Model. EEMs were inspected for instrument error or other phenomena that could disrupt the modeling process. Two samples were removed from the dataset to create a final set containing n=52 EEMs. From this dataset, 3, 4, and 5 component models were split half validated according to (Stedmon and Bro, 2008). A summary of the diagnostic information of the validated models is shown in **Table 8**.

# of Components	Split Half Validated	Random Initialization Analysis SSE	Core Consistency %
3	Yes	256	39.86
4	Yes	145	70.76
5	Yes	91	46.51
6			
7			

Table 8 – Summary of diagnostic information from 3, 4, and 5 component models

The Random Initialization Analysis results and core consistencies of the models were evaluated in the same way as the Total Model. The Random Initialization SSE values showed moderate improvement between each model, but the core consistencies showed the 4 component model to be superior.

The core consistency diagnostic yielded poor results for the 3 and 5 component models. The drop in core consistency between the 4 and 5 component models hinted that the 5 component model was overfitting the data.

The 3 component model has shown poor SSE and poor core consistency and is therefore considered non suitable. To select between the 4 and 5 component models, the components themselves were evaluated to see if they exhibited common fluorophore patterns recommended by Murph et al. (2013) and appear to be fitting peaks rather than noise. The 5 component model identified an unusual peak located at excitation/emission <240/380nm and is shown in **Figure 8**. Peaks in this region of the spectra are often considered to be part of larger components with another more clearly resolved peak (Murphy et al., 2013; Stedmon et al., 2011; Yu et al., 2015).

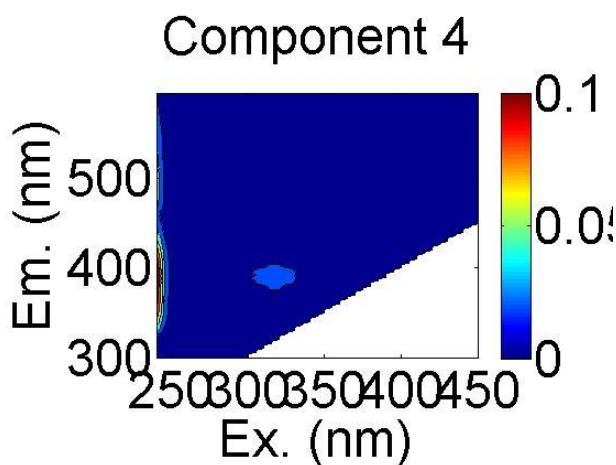

Figure 8 – Component 4 of the 5 component model

Component 4 in the 5 component model showed two emission wavelengths and the lesser, higher wavelength was in the same location as the peak in component 2. This, coupled with the low core consistency of the 5 component model, seems to indicate that the 5 component model was overfitting the data and had created a component that does not exhibit typical fluorophore patterns. Therefore, the 4 component model appeared to be the most appropriate model and was used in this study.

Data Analysis

Preliminary investigation of the data was carried out graphically in Excel (2013). Relationships between chemical parameters, PARAFAC component loadings, and component loading ratios were evaluated by linear regression and Pearson's R. Means based on sample source were also investigated graphically. Mean plots with standard deviation error bars were created to determine potentially interesting differences in source water quality.

Potentially interesting trends, relationships, and mean characteristics were examined statistically using R (3.3.1). Significance values were calculated for each linear regression coefficient and to determine significant differences in means. For regression plots and tabulated data, refer to **Appendix A - Supplementary figures**.

Contamination Detection Limit

Near the end of the sampling period (9/14/2016) a 1L sample was collected from both the effluent and the oxic tank. These samples were filtered and used to create a series of oxic tank additions to the effluent sample. Additions were made in triplicate at the following percents: 0%,

2%, 4%, 6%, 8%, 10%, 20%, 30%, 40%, and 100%. Same day effluent and oxic pairs from throughout the sampling period were used to create four additional replicates of each concentration (excluding 0% and 100% oxic water) along this gradient. This was to examine the impact that varying DOM concentrations over time would have on determining the detection limit. The oxic tank additions correspond to additions from 0.1-5.0mg C/L.

EEMs were collected from the created samples using the same methods described above. The Total Model and Effluent Model were applied to the EEMs. Component loadings from each model were examined to determine the parameter that would yield the lowest detection limit, defined as the additional TOC required to change the fluorescence characteristic of a sample two standard deviations from the mean of the pure effluent samples. Additionally, indices typically taken from EEMs and single point fluorescence data were examined for potential breakthrough monitoring capability.

These analysis use regressions to determine where the fluorescence parameter exceeds two standard deviations from the mean effluent parameter. In order to capture the uncertainty of this estimate, the 95% confidence interval for the regression was calculated according to

$$\hat{y} \pm t_{crit} \times s_{yx} \sqrt{\frac{1}{n} + \frac{(x - \bar{x})^2}{SS_x}}$$

where the values of the regression, \hat{y} , are bound by t_{crit} times the sample standard error of the series of dilutions used to create the regression (Zaiontz, 2016).

Chapter 4 - Results and Discussion

Data collection of the MBR system took place from late March, 2016 through the end of August. The system showed a high capacity for nutrient removal throughout the sampling period (

	Influent	Oxic Tank	Effluent	% Removal
Total Nitrogen (mg/L)	58.8 ± 16.6	504.2 ± 259.2	8.3 ± 7.5	85.9 ± 81.5
Total Phosphorus (mg/L)	7.2 ± 2.4	203.9 ± 112.4	4.3 ± 1.9	41.7 ± 23.2
Chemical Oxygen Demand (mg/L)	285.7 ± 203.69	N/A	23.6 ± 24.3	91.7 ± 115.2
Total Organic Carbon (mg/L)	35.3 ± 25.4	17.4 ± 18.4	9.6 ± 7.1	72.8 ± 75.3

Table 9). The highest and most consistent removal occurred for nitrogen, while phosphorus showed the lowest and least consistent removal.

The oxic tank showed a high concentration of nitrogen and phosphorus compared to the influent or effluent. This build up seems to reflect the capacity of the bacteria and floc in the oxic tank to quickly absorb or retain valuable nutrients. This phenomenon is clearly seen by examining changes in nutrient concentrations over time and is covered in the following section.

	Influent	Oxic Tank	Effluent	% Removal
Total Nitrogen (mg/L)	58.8 ± 16.6	504.2 ± 259.2	8.3 ± 7.5	85.9 ± 81.5
Total Phosphorus (mg/L)	7.2 ± 2.4	203.9 ± 112.4	4.3 ± 1.9	41.7 ± 23.2
Chemical Oxygen Demand (mg/L)	285.7 ± 203.69	N/A	23.6 ± 24.3	91.7 ± 115.2
Total Organic Carbon (mg/L)	35.3 ± 25.4	17.4 ± 18.4	9.6 ± 7.1	72.8 ± 75.3

Table 9 - Mean nutrient levels for each stage of the MBR system. Percent removal is calculated from the difference in quality of sample pairs from the influent and effluent.

Detailed water quality data from the effluent revealed that the system generally produced high quality effluent. However, the effluent did not meet all EPA standards for unrestricted reuse or release to groundwater.

	Effluent	EPA Standard ¹
Total Nitrogen (mg/L)	8.3 ± 7.4	
Ammonium Nitrogen (mg/L)	2.3 ± 5.7	
Nitrate Nitrogen (mg/L)	5.2 ± 3.6	
Ortho-Phosphorus (ppm)	3.9 ± 1.9	
Total Phosphorus (mg/L)	4.2 ± 2.0	
Total Coliforms (MPN/100mL)	1.6 ± 3.0	non-detectable CFU/100mL ^{2,3}
E. Coli (MPN/100mL)	0.1 ± 0.6	non-detectable CFU/100mL ^{2,3}
pH	6.5* ± 0.7	6-9 ²
Conductivity (mS/cm)	0.6 ± 0.2	
Turbidity (mNTU)	161.2 ± 692.5	2 NTU ^{2,3}
Dissolved Oxygen (mg/L)	4.1 ± 2.4	
UV transmittance	74.1 ± 2.9	
Chemical Oxygen Demand (mg/L)	23.6 ± 24.3	
Total Organic Carbon (mg/L)	9.6 ± 7.1	2mg/L ³

Table 10 - Mean effluent water quality and applicable EPS standards.

2 – Standards for unrestricted urban reuse or release to impoundment

3 – Standards for release to groundwater

* – Prior to apparent instrument failure

A greater understanding of the system’s performance can be achieved by examining collected water quality data over time. As alluded to above, the buildup of nitrogen and phosphorus in the oxic tank takes place over time. Several other water quality measurements also change over time, whether over the course of the study or over the course of a pumping cycle.

Temporal Variation in MBR Function

Temporal variations in MBRs have been studied for the past decade (Zhang et al., 2006) (Hur et al., 2014; Maqbool et al., 2016, Zhang et al., 2006). These recent studies have largely focused on membrane fouling, but the present work focuses on how temporal variations can influence the monitoring of an MBR system, specifically monitoring by fluorescence spectroscopy. It has been reported that MBR systems undergo a startup period during which the bacteria in the oxic tank colonize their new environment and a biofilm develops on the membrane surface (Drews, 2010; Hur et al., 2014; Kraume et al., 2009; Zhang et al., 2006). This startup period is often defined in terms of the trans-membrane pressure of the system (Hur et al., 2014). The present study collected a wide variety of water quality parameters. The relationships between the collected parameters and time are either shown below or in **Appendix A: Supplementary figures**.

Shortly prior to the beginning of this study, the MBR system was cleaned with bleach and re-seeded with a live culture of wastewater. Due to this, the beginning of the study was characterized by a dramatic acclimatization of the sludge to the MBR system. This process was accompanied by an increase the trans-membrane pressure (TMP) of the system. The TMP increased with operating time according to an observable pattern. The TMP of the MBR in the present study increased during an initial startup period and held relatively constant throughout the remainder of the study period (**Figure 9**). This maturation is evident in water quality measurements as well as in fluorescence components. The startup period prior to this gray dashed line is referred to hereafter as the TMP startup period.

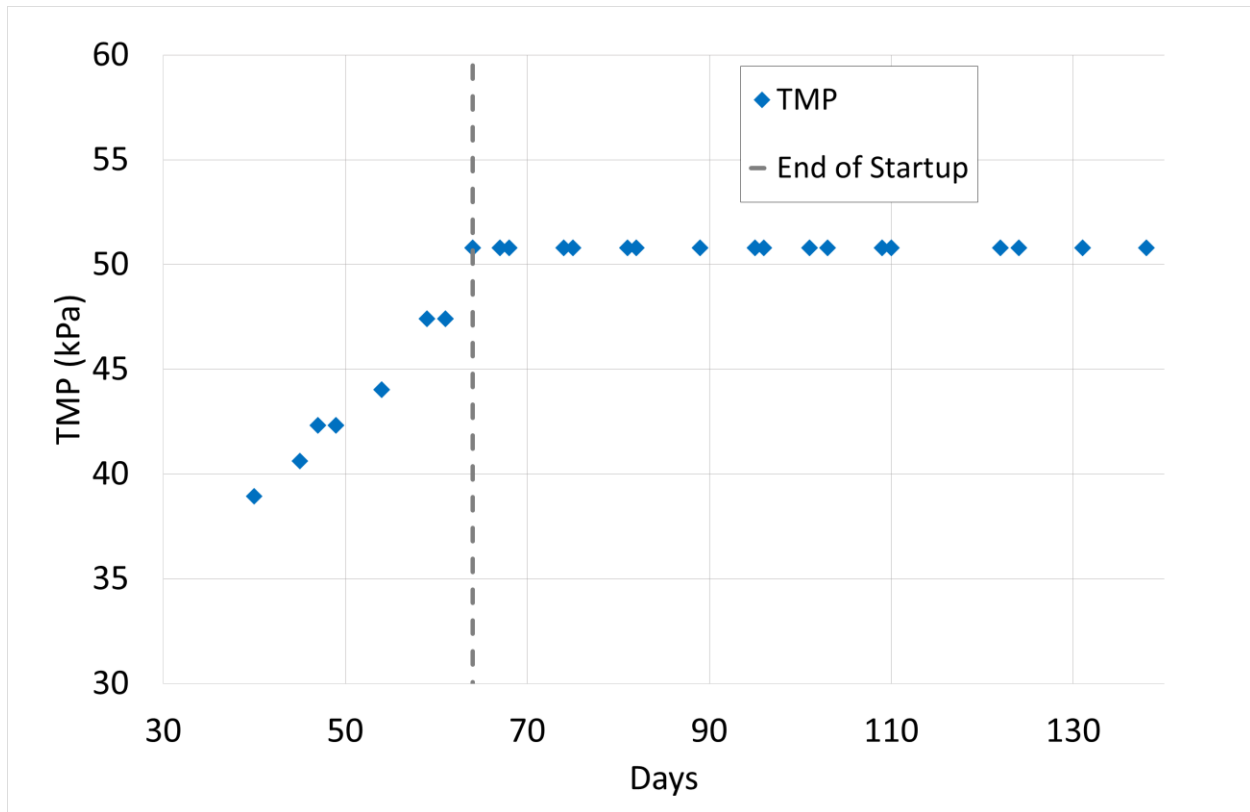

Figure 9 - Transmembrane pressure of MBR over time

Total nitrogen in the effluent showed the clearest reflection of system maturation during this startup period. At 61 days the effluent nitrogen concentration leveled off. As the seeded microorganisms acclimatized to their new environment, growth increased and fewer nutrients escaped from the system. It is also known that as a layer of sludge builds up on the membrane surface, called the cake layer, the effective pore size decreases, which can have the effect of increasing effluent quality (Mafirad, Mehrnia, Azami, and Sarrafzadeh, 2011). Both of these effects can be seen in **Figure 10**. The development of the biofilm on the membrane coincides with the decrease and leveling off of turbidity coming through in the effluent. It is unclear why there would be turbidity coming through the membrane since the pore size is $0.2\mu\text{m}$, but apparently the biofilm layer was effective in reducing the turbidity.

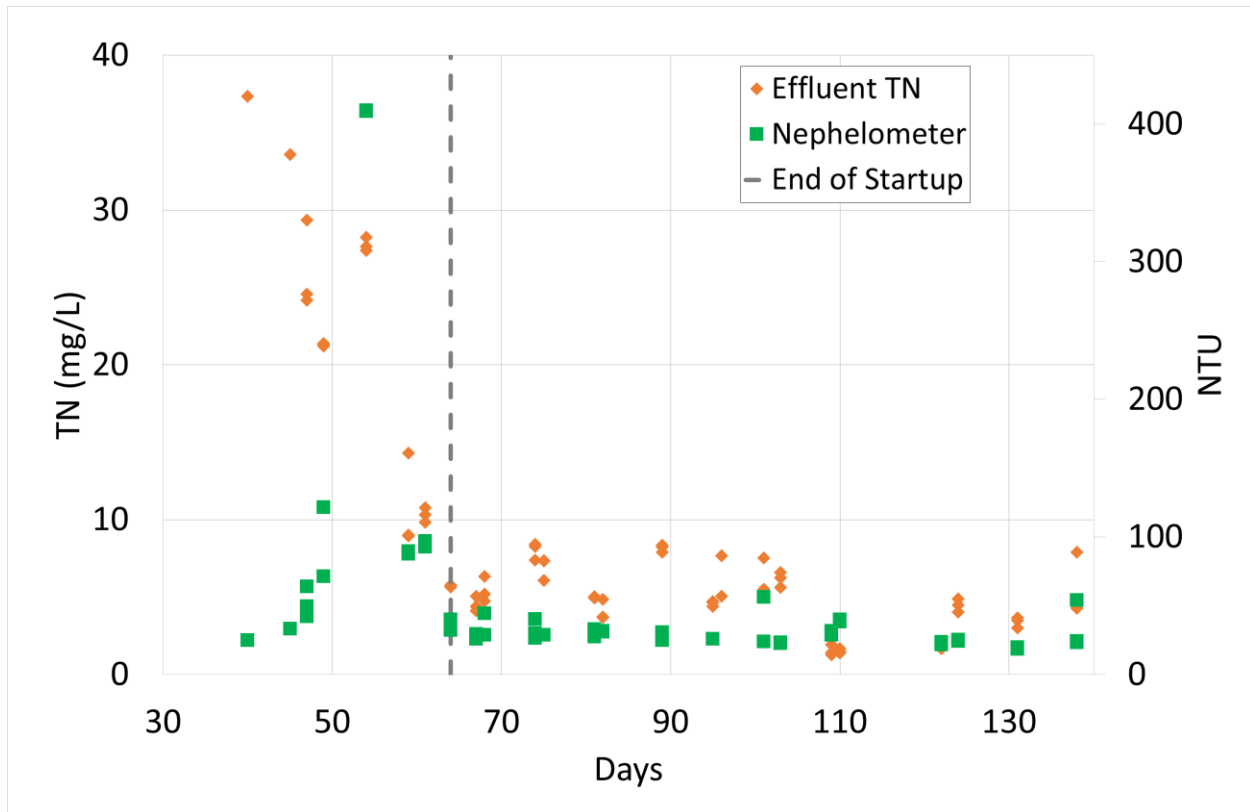

Figure 10 - Effluent total nitrogen and turbidity vs days. Dotted line shows day 61

Interestingly, there was an analogous startup phase in the oxic tank. Total nitrogen and total phosphorous are the clearest indicators of system maturation. The initial rise and then leveling off of these nutrients can be seen in **Figure 11**. The gray dashed line is the end of the startup period as determined by effluent quality and TMP. The black line demarks an apparent end of oxic tank quality development. This startup period related to oxic tank conditions is referred to as the oxic startup period.

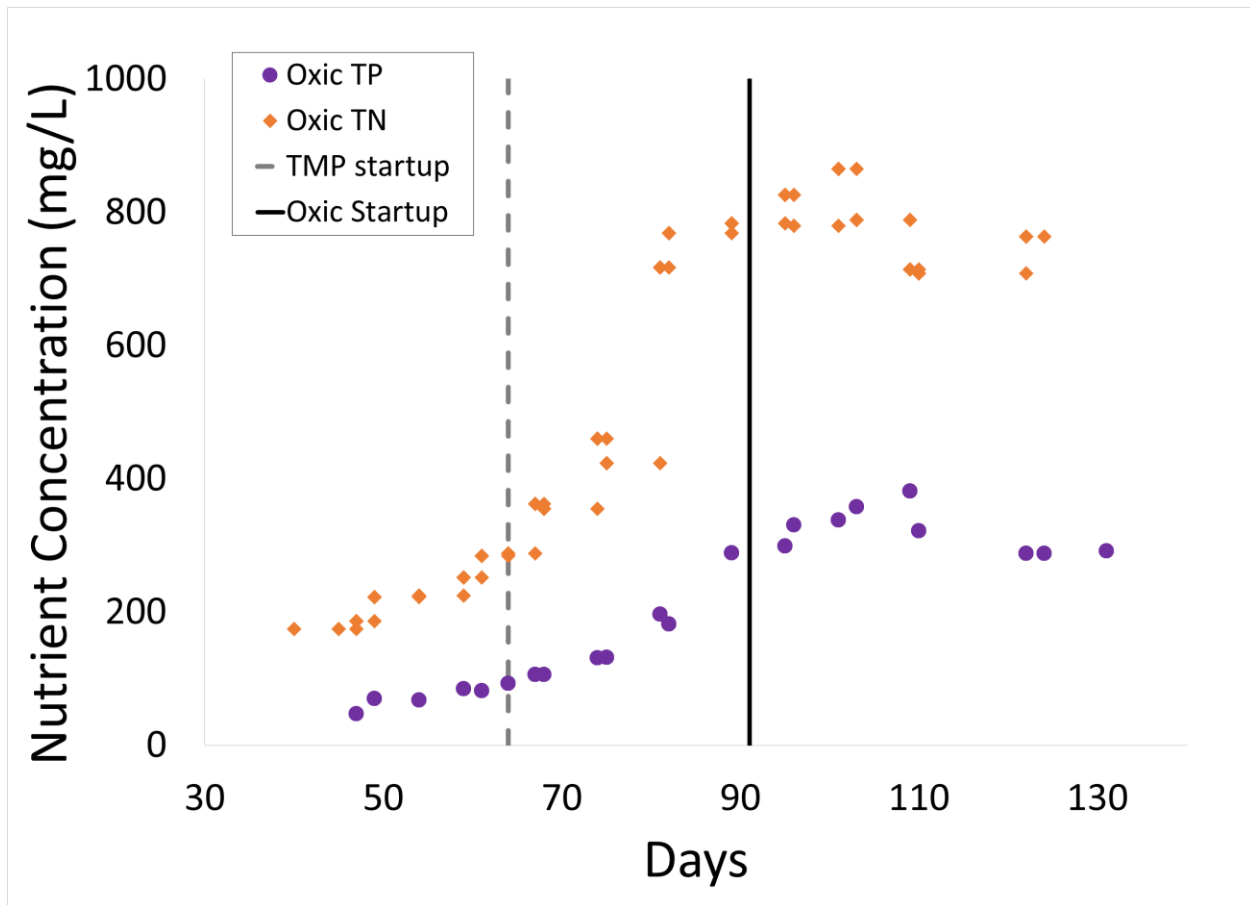

Figure 11 - Total nitrogen and phosphorus vs days the system has been running. Gray dashed line is the end of the TMP startup period and black vertical line is the end of the oxic tank startup period.

The effluent TN decreased and then leveled off as the oxic tank TN began to rapidly increase. This information supports the idea that the TMP startup period is when the biofilm layer develops on the membrane surface. The initial drop in effluent TN may have been caused by the capture of nitrogen by the biofilm. This nitrogen was then retained in the biofilm until cells died and lysed, releasing the nitrogen back into the oxic tank. This retention and release could cause the increase in TN in the oxic tank far beyond influent TN levels. For reference, the TN and TP levels for each source over time are shown in **Figure 12**. It can be seen that the oxic tank TN and TP levels far surpass those of the influent.

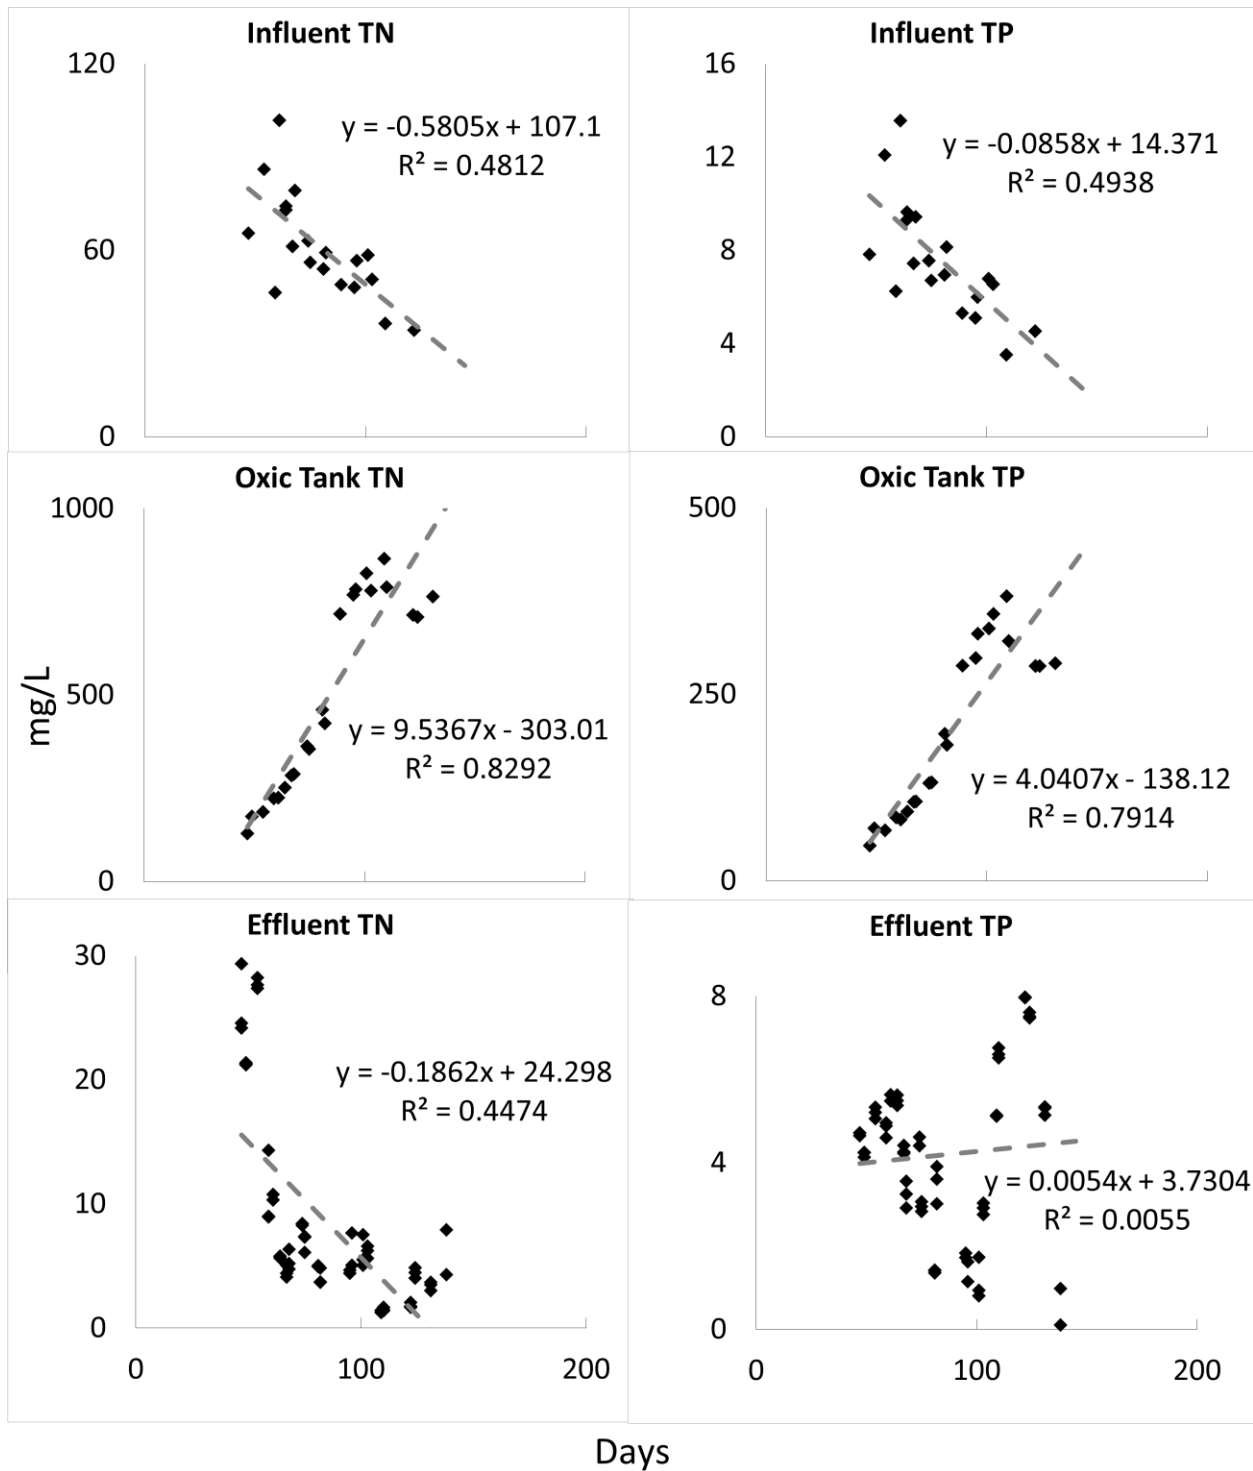

Figure 12 - TN and TP over time from each source. From top to bottom: influent, oxidation tank, effluent

Variation over a Pumping Cycle

In addition to changes over a several month scale during the study, some parameters measured also changed throughout a pumping cycle. Total coliforms is a routinely checked water quality parameter because it is an indicator of fecal contamination of waters. In this study, coliforms showed a relationship to filtration time (**Figure 13**). There was a distinct peak in total coliforms for samples collected within five minutes of the beginning of a pump cycle. This indicated that effluent quality may change over a pumping cycle. In the case of coliforms, this is likely related to the membrane biofilm layer. It is possible that the biofilm layer increased in thickness or density over the course of the pumping cycle as more material was drawn through it, thereby decreasing the amount of coliforms able to slip through the membrane. This phenomenon has been reported previously (Mafirad, Mehrnia, Azami, and Sarrafzadeh, 2011).

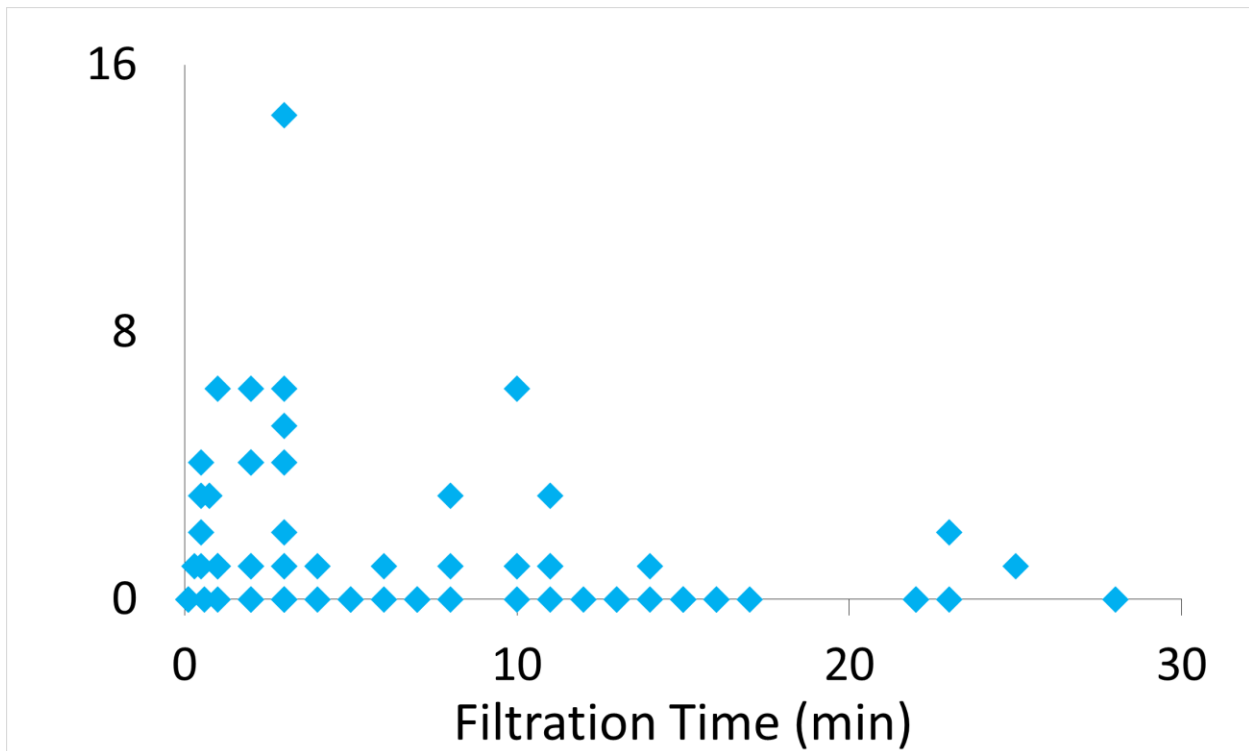

Figure 13 –Filtration time vs total coliforms for the entire startup period.

Since effluent quality was not only evaluated from grab samples, but was also monitored continuously via online instruments, these parameters were also investigated for changes over a pumping cycle. **Figure 14** shows the variations in different water quality parameters measured from the effluent line in the MBR system over the course of a week.

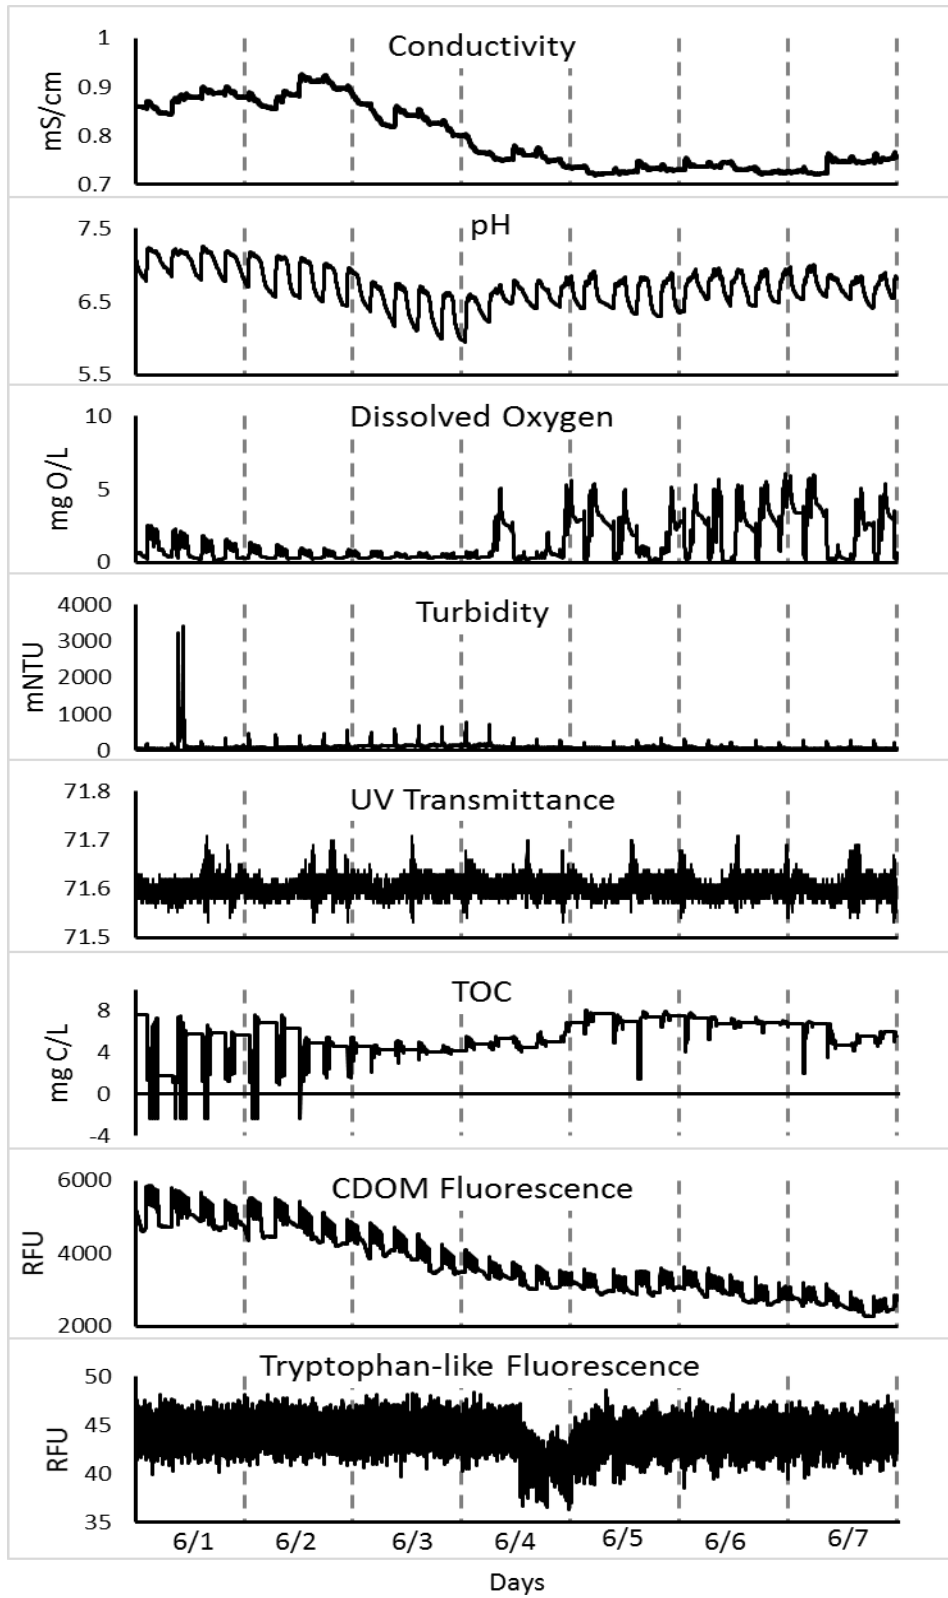

Figure 14 - Online measurements over time from 1-Jun thru 7-Jun. Dashed lines indicate days.

The cyclic nature of these data corresponded to the activation of the effluent pump. When the pump turned on, a pulse of water traveled through the instruments that was initially turbulent, then returned to laminar flow. Each instrument responded to this pulse differently.

Conductivity, turbidity, and TOC showed a sharp peak when the effluent pump started, while CDOM fluorescence, pH, and DO showed elevated values while the system was filtering and then dropped off as the water through the system stagnated between pumping periods. Additionally, the UVT and tryptophan fluorescence showed variation, but this did not appear to correlate with the pumping cycle. If using online monitoring for contamination detection or treatment monitoring, these effects must be considered on an instrument by instrument basis to allow for correct interpretation of the data.

Another effect that may impact successful online monitoring is instrument maintenance. The CDOM instrument showed little drift in **Figure 14**, but the value changes dramatically over the course of the study, decreasing according to a power law function. It appeared that the lamp intensity was diminishing rather than reflecting the character of the effluent, but this was not certain (**Figure 15**).

Figure 15 - CDOM intensity over the course of the study. Gray dashed line is effluent startup period. Black line is oxalic tank startup period.

It is possible that the online CDOM instrument was yielding useful information rather than instrument failure. In fact, total nitrogen showed a similar decrease over time. **Figure 16** showed a strong correlation between total nitrogen and CDOM, indicating that the CDOM instrument was producing valid data. However, the CDOM fluorescence wavelengths were also measured from effluent grab samples (also shown in **Figure 16**). The two CDOM measurements did not correlate well.

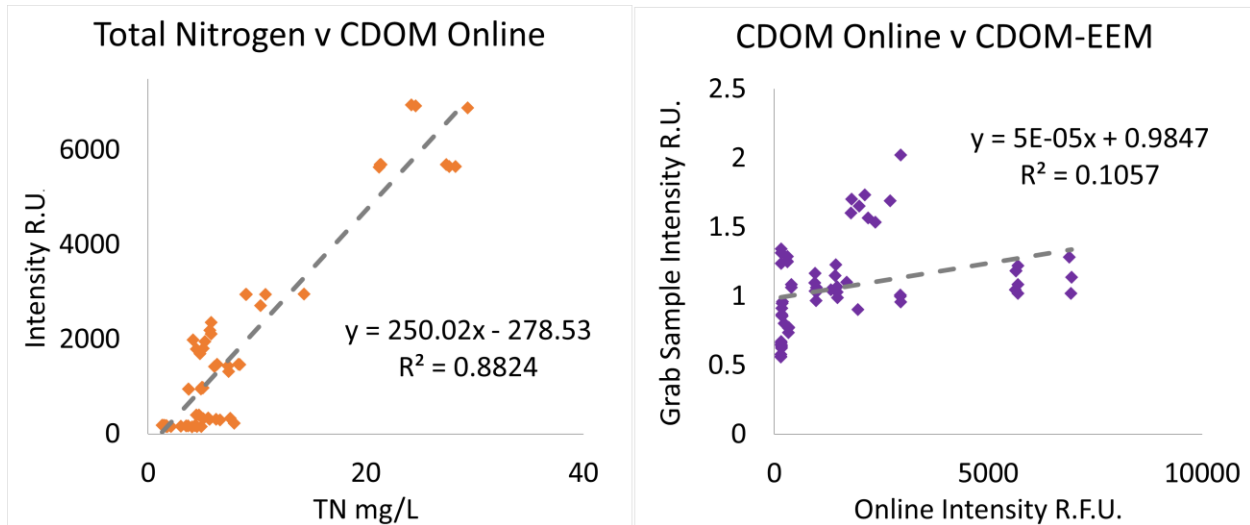

Figure 16 – Left: correlations between total nitrogen and CDOM fluorescence from the online probe (CDOM Online). Right; correlations between CDOM fluorescence from the online probe and grab samples (CDOM-EEM)

The other online fluorescence instrument measured the tryptophan-like peak. This instrument did not show the same clear decrease over time as the CDOM online peak, but did initially dropped and reached a low point at day 100 (**Figure 17**). This similar initial decrease in intensity and the correlation between the online CDOM fluorometer and total nitrogen indicate that the instrument was reflecting actual effluent quality. This indicated that one of the two measurements in each case was erroneous, or that the water measured by the benchtop fluorometer and online fluorometers were not of the same quality. This may be possible since bacterial growth was present in the effluent line after the sampling port and before the CDOM probe, however this distance was short (2ft.). It was therefore unclear whether the instrument was reflecting actual water quality or a lamp failure in both instruments.

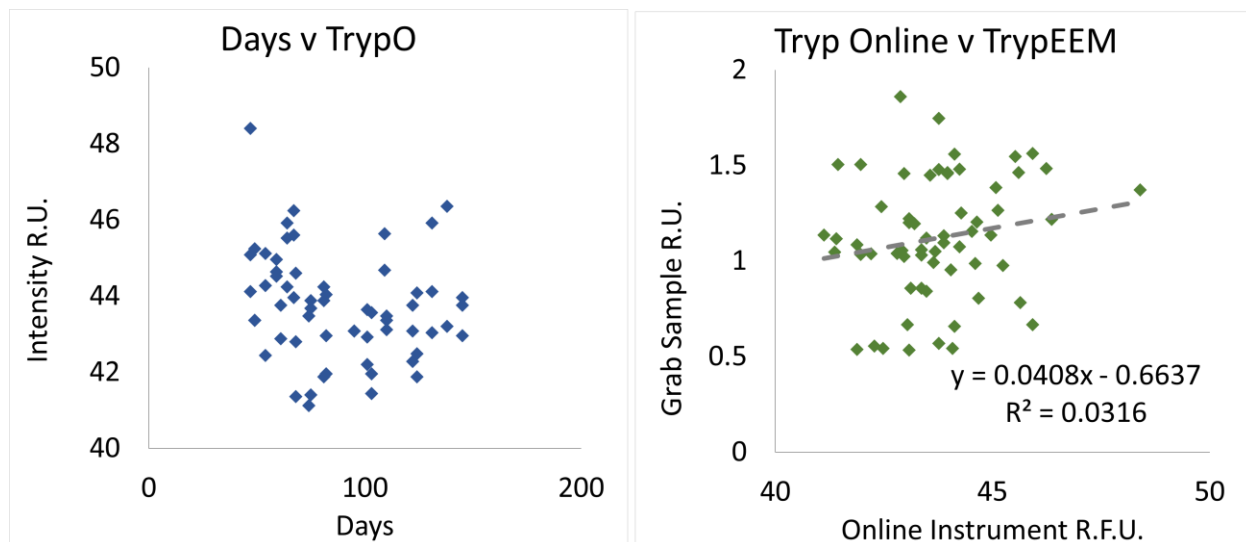

Figure 17 - Left; online tryptophan peak intensity over time. Right: correlation between online tryptophan peak and grab sample tryptophan peak.

PARAFAC

Samples taken from throughout the MBR treatment system were used to create two PARAFAC models. The Total Model was created using samples from each sampling location ($n = 198$) while the Effluent Model, used in the contamination detection study, was created solely from effluent samples ($n = 65$). Broad humic fluorescence was present in all samples with variable protein related fluorescence present depending on the source of the sample. The Total Model contained five commonly observed components. The Effluent Model consisted of four of these five components. The components were identified relative to common components published in other studies and the traditional peak locations identified by Coble (1996) (**Table 11**).

A comparison of the spectral loadings are shown below in **Figure 18**. Components 1-4 of the Total Model overlap closely with C1-C4 of the Effluent Model. This indicated that the Total Model was well able to discern the components necessary to model the effluent within a diverse

group of samples. This is the strength of the PARAFAC technique (Yu et al., 2015). **Figure 19** shows an EEM of each component. The Total Model on the left contains four components nearly identical to the components that make up the Effluent Model.

Total Model	Effluent Model	Component Reference	Peak Reference ⁵
Component 1 240 (305)/396	Component 1 240 (295)/394	G2 ¹ - microbial humic-like, <250, (320)/400 G1 ³ - wastewater related microbial humic, 230 (305)/414 C2 ² - productive oceanic environments and high nutrient agricultural runoff 315/384	Peak M - marine humic, 290-325/370-430 Peak A - UV humic-like, 260/400-460

- 4 - (Stedmon, Markager, and Bro, 2003)
- 5 - (Coble, 1996)

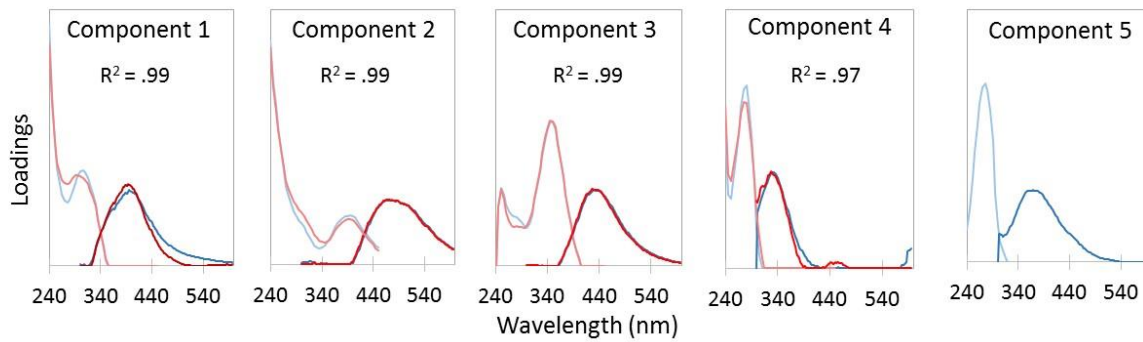

Figure 18 - Comparison of spectral loadings between the Total Model and Effluent Model. Excitation spectra are to the left of emission spectra and are lighter. Total Model spectra are blue, Effluent Model is red.

Figure 19 - Component EEMs for Total Model (left) and Effluent Model (right)

Component 1 is microbial in origin and has been associated with wastewater impacted sources (Yu et al., 2015). This component is similar to peak M described by Coble (1996). This region of the spectra was originally referred to as marine humic-like, but has since been shown to relate to microbial activity (Stedmon and Markager, 2005). Component 2 is seen in diverse environments and is thought to relate to terrestrially derived high molecular weight humic substances (Stedmon et al., 2003). This component overlaps with peak A, which is the low excitation wavelength humic-like peak. Component 3 appears ubiquitously in natural waters (Yu et al., 2015) and showed humic-like characteristics similar to peak C (Stedmon et al., 2003). This component has a broad peak centered at excitation/emission 350/425nm and is responsible for the broadest feature present in this set of EEMs, indicating the diversity of chemicals represented by the component. Component 4 exhibits fluorescent character similar to tryptophan and is protein like compounds (Yamashita and Tanoue, 2003). This region of the EEM is referred to as peak T, however this component also overlaps with peak B, the tyrosine related peak (Coble, 1996). Component 5 also exhibits fluorescence in the tryptophan-like region, but is centered at a slightly higher wavelength pair (Murphy et al., 2011; Stedmon et al., 2003). In spite of the potential shift, this component has been reported in this location by Yang et al. (2014) and has been generally referred to as amino acid related or protein like (Yang et al., 2014; Yu et al., 2015).

Mean Component Loadings

The average component loadings over the course of the study were calculated for each source (**Figure 20**). The loadings from the Total Model were used for this calculation. Due to higher DOM concentrations, the influent had higher loadings for all components. This may have

also reflected the less degraded nature of the organic matter entering the system. The loadings of the oxic tank generally decreased from the influent, and the effluent loadings decrease from the oxic tank. This trend reflects the decreasing DOM concentrations through the treatment process. The effluent loadings were generally the lowest.

The oxic tank had a much larger loading of C4 than the effluent, which indicated that some process occurring on or within the filter was responsible for the removal of C4. Similarly, the influent had a much larger loading of C5 than the oxic tank, which indicated that C5 was removed by a process occurring in the oxic tank.

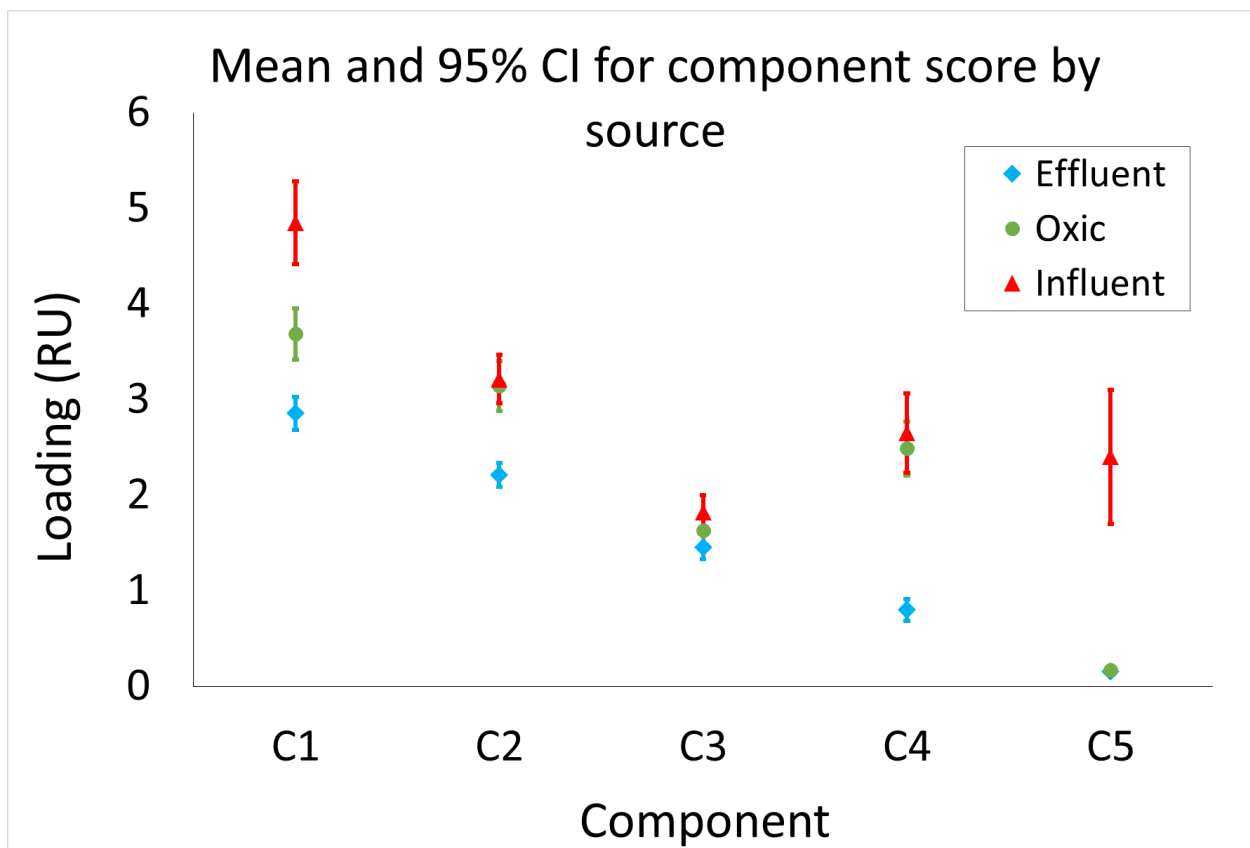

Figure 20 - Mean component loadings (Total Model) and 95% confidence intervals for each source

It was expected that the bioreactor portion of the MBR system would more effectively remove protein related components than humic-like components. As reported elsewhere (**Table 5**), bioreactors have been shown to reduce protein related fluorescence peaks T₁ and T₂. It was not expected that tryptophan-like C₄ would be removed during the filtration process. It is possible that another process on the filter surface was responsible for the removal of this component.

Percent Distribution of Components

In order to remove the potential effects of changing CDOM concentrations, the percent distribution of the component loadings for each source were calculated (**Figure 21**). The percent distribution of each component was calculated as:

$$\% \text{ distribution} = \frac{(\overline{SCN}) \times 100}{\sum_{n=1}^5 \overline{SCn}}$$

where *S* denotes the source and may be *E* for effluent, *O* for oxic, *I* for influent. *C* denotes that the variable is a component score. *N* is a number from one to five indicating which component's percent distribution is being calculated, and *n* is a variable with a value from one to five indicating which of the five components is being considered.

The same trends were present within each source in this view of the data. Note that the percent of a given component cannot be compared across sources here. This is because the total amount of CDOM or total fluorescence may have been (and likely was) different between sources.

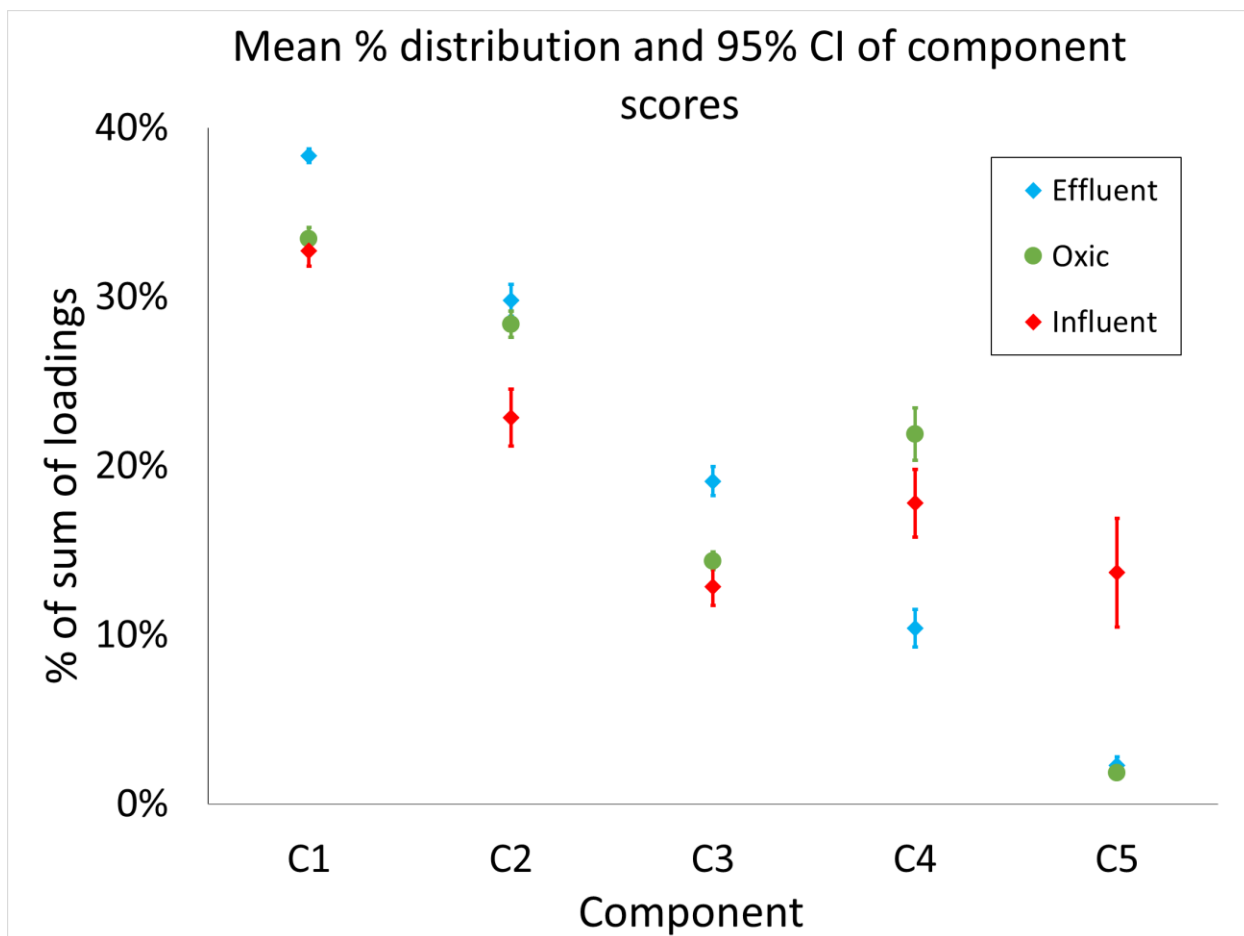

Figure 21 - Percent distribution of component loadings for each source.

Changes in DOM concentrations can influence component loadings by changing the amount of fluorescent material present in the water. This may interfere with data interpretation. It was prudent to examine loadings without the potential influence of changing concentrations of fluorescent matter.

When considering the distribution of the loadings within a source, the relative loadings were the same. Comparing the distribution of loadings between sources should be done with caution, due to the effect of changes in DOM concentration. The effluent generally had higher percent loadings of the humic-like components than the oxic tank, and the oxic tank had higher percent loadings of the humic-like components than the influent. However, this does not mean

that there was more fluorescent humic-like DOM in those sources than in the influent. This effect was a result of the removal of the protein related components C4 and C5 and the resulting decrease in total fluorescence in the effluent and oxic tank samples.

Temporal Variations in Fluorescence

There have been limited attempts to use fluorescence to investigate changes in MBR water quality over time, all of which were at benchtop or pilot scale (Hur et al., 2014; Maqbool et al., 2016; Zhou et al., 2012). In each case, the fluorescence character of the effluent changed minimally over time, while changes from within the reactor were more obvious. These changes over time reflected a cake layer formation on the membrane surface, thus dividing the membrane system performance into two periods, cake layer formation and afterward (Hur et al., 2014; Maqbool et al., 2016).

While these studies offer guidance, additional research has shown that lab scale experiments mostly offer qualitative information in regards to operation of full scale MBR systems (Kraume et al., 2009). Research suggested this was due to differences in hydrodynamic conditions, sludge freshness and composition, ambient conditions, and energy input (Kraume et al., 2009). This study allowed for investigation of temporal variations of a full scale MBR system by fluorescence spectroscopy. A notable finding in this study and others is the presence of two different start up periods related to membrane performance: the effluent startup phase defined by TMP and reflected in TN and turbidity (via the nephelometer), and the oxic tank startup phase defined by the TN and TP of the oxic tank. Evidence of these phases was also seen in the fluorescence characteristics of the system.

Figure 22 shows composite component loadings for the effluent, oxic, and influent samples taken over time. The composite loadings are the mean loading from the three samples collected from that source on the given day. Taking the mean of the three loadings from a set of concurrent samples helps to minimize the effect of outlier samples and to trim the data to a manageable number of data points. The gray and black lines represent the TMP and oxic tank startup period, respectively. The observed changes over time are related to variable influent quality, development of the sludge character in the oxic tank, and development of the biofilm on the membrane surface. As **Figure 22** reveals, the data are complex, but there does appear to be trends to the variation.

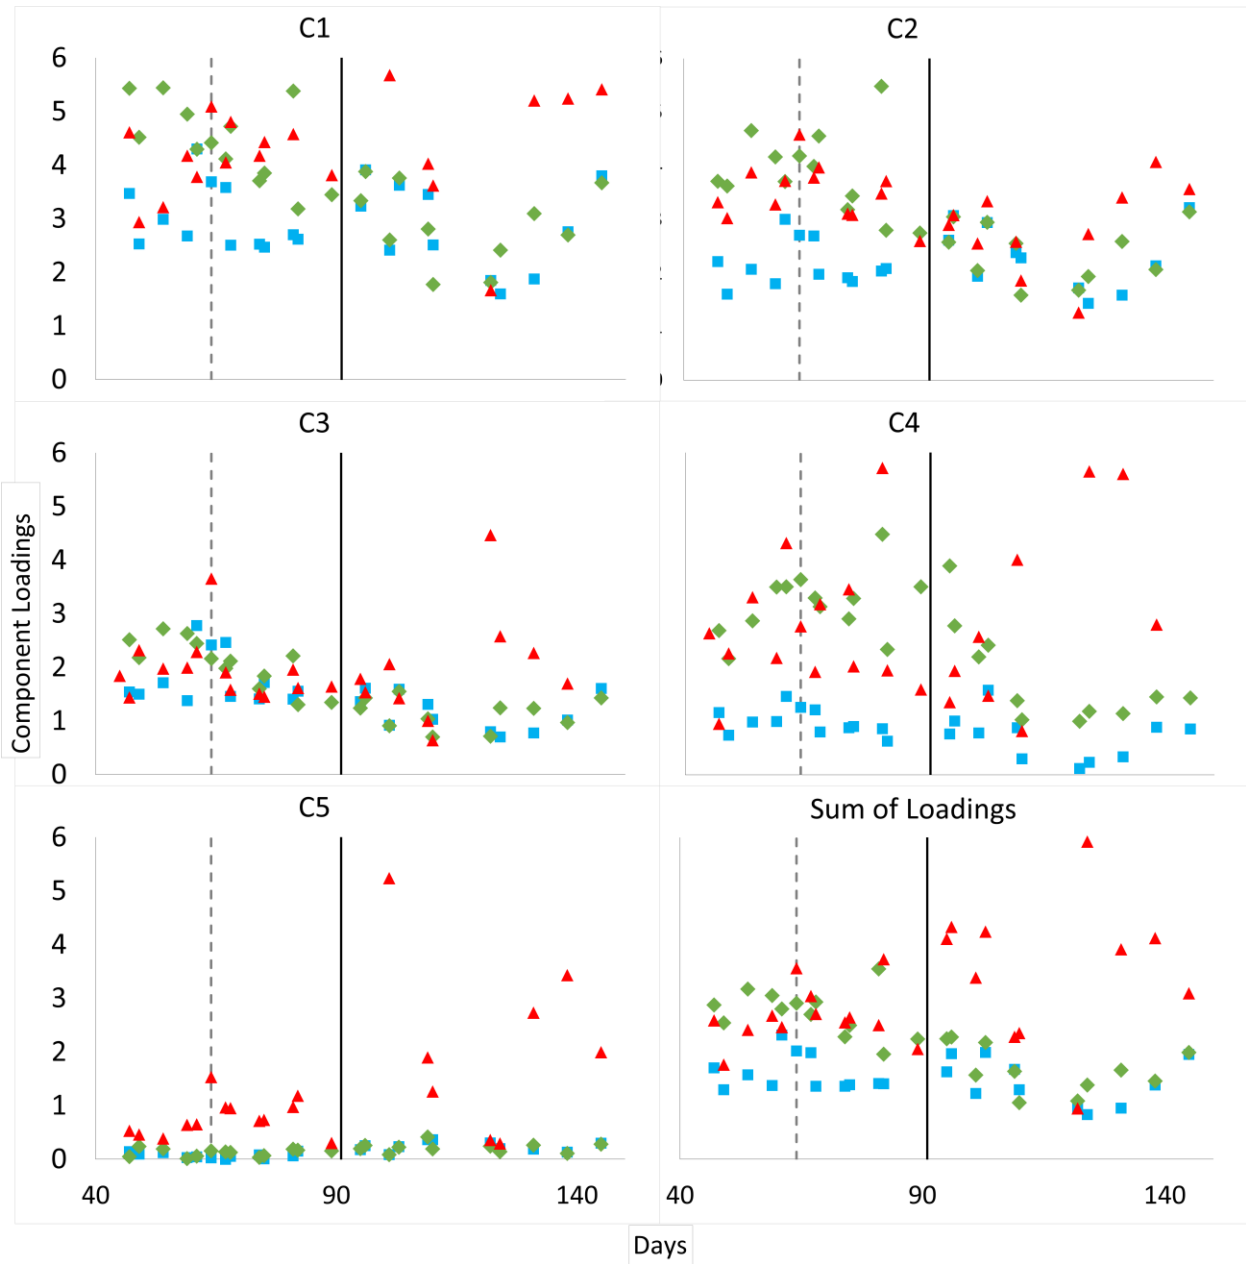

Figure 22 – Composite component loadings over time by source. Effluent components are blue squares, oxalic tank components are green diamonds, and influent components are red triangles. Gray dashed line denotes TMP startup period and black vertical line denotes oxalic startup period

There are not many clear trends when only considering individual components, but there are some. Humic-like components C1, C2, and C3 decrease over time in the oxalic tank (green diamonds). These same components also have an increasing tail near the end of the sampling

period, starting around day 125. Terrestrial humic-like C2 also exhibited this hockey stick shaped trend in the influent (red triangles), which may be a cause to the trend in the other humic-like components. Also in the influent (red triangles), amino acid related component C5 increased after the oxic tank startup period.

Looking at trends in individual components, however, can be misleading. Each of the sample sources are influenced by the quality of the water coming from previous sources. For example, terrestrial humic C2 decreased in the oxic tank (green diamonds) during the same period that C2 decreased in the influent (red triangles). It is not possible to determine a cause for this decreasing trend, but it is likely that the trend in the oxic tank is related to the trend in the influent. Therefore, comparisons between the component loadings are more valuable as these can take into account the water quality upstream of the source being considered.

Removal of PARAFAC components over time

Figure 22 is useful for examining the differences in component loadings and assessing the removal or buildup of components over time. Differences between influent loadings (red) and oxic tank loadings (green) may indicate that a component is biodegraded or retained in the oxic tank. Similarly, differences between oxic tank loadings (green) and effluent loadings (blue) may indicate that the biofilm on the filter is removing a component or leeching it through the filter.

In the period between water entering the MBR system as influent and travelling through the oxic tank, the only process that may influence the DOM is biodegradation since settling is minimized by a mixing pump and blower within the MBR system. From the reactor, through the membrane, to the effluent there are three processes that may affect DOM. These are adsorption to the membrane surface, biosorption into the matrix of bacteria and organic material (biofilm)

forming on the membrane surface, and biodegradation by the biofilm. The TMP startup period was defined as a period of increasing TMP (up to day 61 in the present study), after which the TMP remained constant for the remainder of the study period. During the TMP startup period, the processes that acted at the membrane surface to remove components were likely the same processes that increased TMP. However, after this period, there was still removal of some components without the effect of increasing the TMP. These processes are discussed below.

Removal of microbial humic C1

During the oxic tank startup phase, microbial humic C1 had a higher loading in the oxic tank (green) than in the effluent (blue) (**Figure 23**). This result indicated that this component was removed by membrane related processes. This phenomenon has been reported previously (Hur et al., 2014; Maqbool et al., 2016). Since C1 was removed by membrane related processes during the TMP startup period, this component may have contributed to increasing the system TMP. Of the potential membrane processes, adsorption to the membrane surface likely has the greatest influence on TMP as this process leads directly to pore narrowing, even prior to the buildup of biofilm (Iorhemen, Hamza, and Tay, 2016).

Figure 23 - Microbial humic C1 loading over time. Gray dashed line indicates end of TMP startup period. Black line indicates end of oxic tank startup period. The source of each component loading is indicated as follows: red triangles represent influent, green diamonds represent oxic tank, blue squares represent effluent.

After the TMP startup period when the biofilm was established, C1 was removed at the membrane surface by a process that did not affect TMP. This was possibly biosorption to the biofilm rather than adsorption to the membrane surface and pore space. This may explain why the TMP stopped increasing. A similar phenomenon was observed by Arora and Davis (1994) and reviewed by Le-Clech et al. (2006). Arora and Davis (1994) added yeast to a MBR containing bovine serum albumin. The yeast was found to create a type of pre-filter that inhibited the BSA from binding to the membrane pores, resulting in greatly decreased membrane fouling.

During the period after the TMP startup and still during the oxic startup period (days 61-91), the oxic tank C1 loading began to decrease, while influent loadings remained high. This indicated a decrease in filter retention over time, which has been previously reported by Maqbool et al. (2016). It appears that as the biofilm was growing, biodegradation began to increase in the oxic tank, eventually dominating the removal of C1.

After the oxic startup period, the oxic tank and effluent loadings for C1 began to mirror each other. It may be that biodegradation in the oxic tank removed the components to such a level that the membrane surface processes no longer removed the material. Biodegradation of C1 has been reported elsewhere (Cohen et al., 2014; Murphy et al., 2011).

Removal of terrestrial humic C2

Terrestrial humic-like C2 exhibited similar patterns of removal as compared to microbial humic C1 (**Figure 24**). During the oxic tank startup phase, this component had higher loadings in the oxic tank (green) than in the effluent (blue), which indicated that C2 was initially removed by membrane related processes, similar to C1. Filtration related removal of C1 has been reported (Hur et al., 2014; Maqbool et al., 2016), but C2 was reported to be resistant to filtration (Ishii and Boyer, 2012). This difference between the results of the present study and those of previous studies may be due to the operational stage of these other systems, which were all past system startup. For example, initially C2 showed removal by filter related processes, but afterward C2 no longer appeared to be retained by the membrane. Since C2 was removed by membrane related processes during the TMP startup period, it too may have contributed to the increasing TMP of the system.

Figure 24 - Terrestrial humic C2 loading over time. Gray dashed line indicates end of TMP startup period. Black line indicates end of oxic tank startup period. The source of each component loading is indicated as follows: red triangles represent influent, green diamonds represent oxic tank, blue squares represent effluent.

During this period after the TMP startup and still during the oxic startup period, the oxic tank loading began to decrease. In the case of C1, this decrease appeared to be due to increasing biodegradation, however C2 appeared to be simply mirroring the influent score. C2 did not exhibit biodegradation until the final days of the study period. Biodegradation of C1 has been reported elsewhere (Cohen et al., 2014; Murphy et al., 2011), but C2 is generally reported to show minimal biodegradation (Cohen et al., 2014; Ishii and Boyer, 2011; Murphy et al., 2011), which is in agreement with the current study.

Removal of microbial humic C3

During the TMP startup phase, microbial humic C3 had higher loadings in the oxic tank than in the effluent (**Figure 25**). This indicated that C3 was removed by membrane related processes. Since C3 was only removed during the period when TMP was increasing, it seems

that this component was only removed by adsorption to the membrane surface. This is consistent with another study which reported the fluorescence peak in the same location as C3 to be found in membrane foulants (Wang et al., 2009).

Figure 25 - Microbial humic C3 loading over time. Gray dashed line indicates end of TMP startup period. Black line indicates end of oxic tank startup period. The source of each component loading is indicated as follows: red triangles represent influent, green diamonds represent oxic tank, blue squares represent effluent.

At the end of the TMP startup period, the effluent loading quickly converged to the oxic tank loading and both closely followed the influent loadings for this component over time. It appears that initially the component was binding to the membrane surface, but after the initial 60 days binding sites to the membrane surface were filled, or conditions in the tank changed that inhibited binding to the membrane surface. This would explain why the effluent loading and the oxic tank loading were approximately the same around day 60. In the instances where the influent brought a higher amount of C3 than usual, the component was biodegraded in the oxic tank to normal levels. Apart from the instances of unusually high C3 inputs from the influent, the

component showed very little biodegradability. This result was consistent with previous literature (Cohen et al., 2014; Murphy et al., 2011).

Removal of tryptophan-like C4

Initially, tryptophan-like C4 removal was entirely accomplished by membrane related processes (**Figure 26**). The removal of this component was consistent through the TMP startup phase (day 1-61) and oxic tank startup phase (day 1-90). Therefore, the component was likely removed by biosorption to the biofilm forming on the membrane surface rather than adsorption to the membrane itself. This result is supported by many studies that found tryptophan-like fluorescence to be related to membrane fouling by biosorption to the biofilm (Hur et al., 2014, Meng et al., 2011; Tang et al., 2010; Wang et al., 2009). If adsorption was the primary process for removal of C4, then the removal would have decreased after the TMP startup period similar to the humic components C1 and C3.

Figure 26 – Tryptophan-like C4 loading over time. Gray dashed line indicates end of TMP startup period. Black line indicates end of oxyc tank startup period. The source of each component loading is indicated as follows: red triangles represent influent, green diamonds represent oxyc tank, blue squares represent effluent.

The transfer from membrane related removal of this component to biodegradation in the oxyc tank does not occur neatly at the end of one of the startup phases, but 10 days or so after the oxyc tank startup period. C4 has been reported to be removed by biodegradation (Baker and Inverarity, 2004) as well as by membrane related processes (Hur et al., 2014; Maqbool et al., 2016). The present study indicated that under different operational stages, the component may be removed by different processes. Initially, C4 was removed by membrane related processes, but afterward the removal switched to biodegradation in the oxyc tank.

While biodegradation of this component increased, examining the percent removal of this component, rather than the absolute removal reveals that the filter was still removing a comparable fraction of this component, but this removal was less obvious because the levels of C4 in the oxyc tank had dropped. This can be seen by comparing the mean component loadings and influent relative component loadings in a later section (**Figure 28**).

Removal of amino acid related C5

C5 is the amino acid related peak and its removal appeared to be entirely accomplished by biodegradation (**Figure 27**). The effluent component loading consistently matched the oxic tank loading indicating no removal from membrane related processes. This is consistent with literature (Yang et al, 2014). Protein like components are considered primarily responsible for membrane fouling due to their retention on membrane surfaces (Drews et al., 2007; Hur et al., 2014; Maqbool et al., 2016). This study has shown one protein like component to be highly biodegradable, while the other is retained by the membrane initially, but is increasingly biodegraded as operation continues.

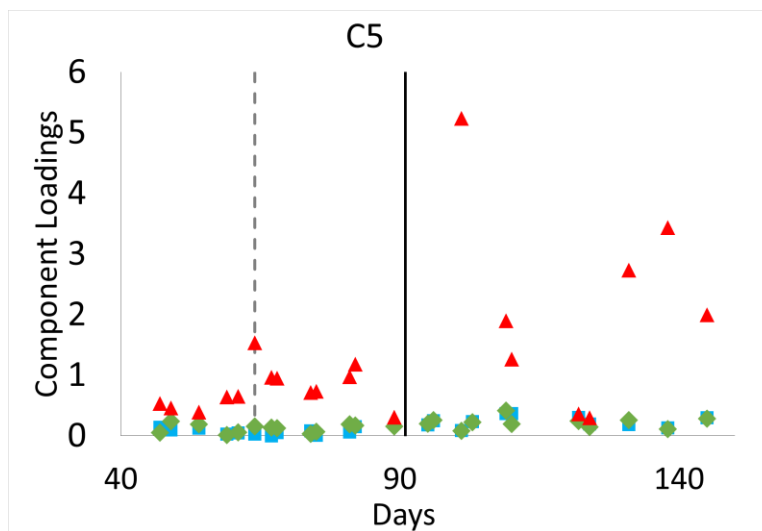

Figure 27 – Amin acid-like C5 loading over time. Gray dashed line indicates end of TMP startup period. Black line indicates end of oxic tank startup period. The source of each component loading is indicated as follows: red triangles represent influent, green diamonds represent oxic tank, blue squares represent effluent.

Relative component loadings

While removals and trends are present in the composite loadings, they are also difficult to visualize. The mean component loadings were taken during and after the two startup periods for easy comparison between startup and afterward and between sources. These means are shown in **Figure 28**. Along with the means are the influent relative component loadings. These were calculated by dividing the component loadings by the corresponding influent component loading from the same day and calculating averages over the four time periods. This presentation of the data removes extraneous information to easily identify the effects that MBR processes have on component scores.

$$\text{influent relative component loading} = \frac{(\overline{SCN})}{\overline{ICN}}$$

An additional advantage of examining component loadings relative to influent component loadings is that effects of changing influent quality on the data are mitigated. One of the differences between a full scale MBR system and a benchtop system is the consistency of influent quality. Often benchtop studies will use synthetic wastewater of a consistent quality throughout the duration of the study (Hur et al., 2014; Maqbool et al., 2016). Since full size MBR systems treating real wastewater encounter variabilities in water quality, this variability could contribute to unexpected system behavior and should be accounted for when analyzing data from real systems. **Figure 28** shows that the same general trends are present when considering component loadings compared to the influent.

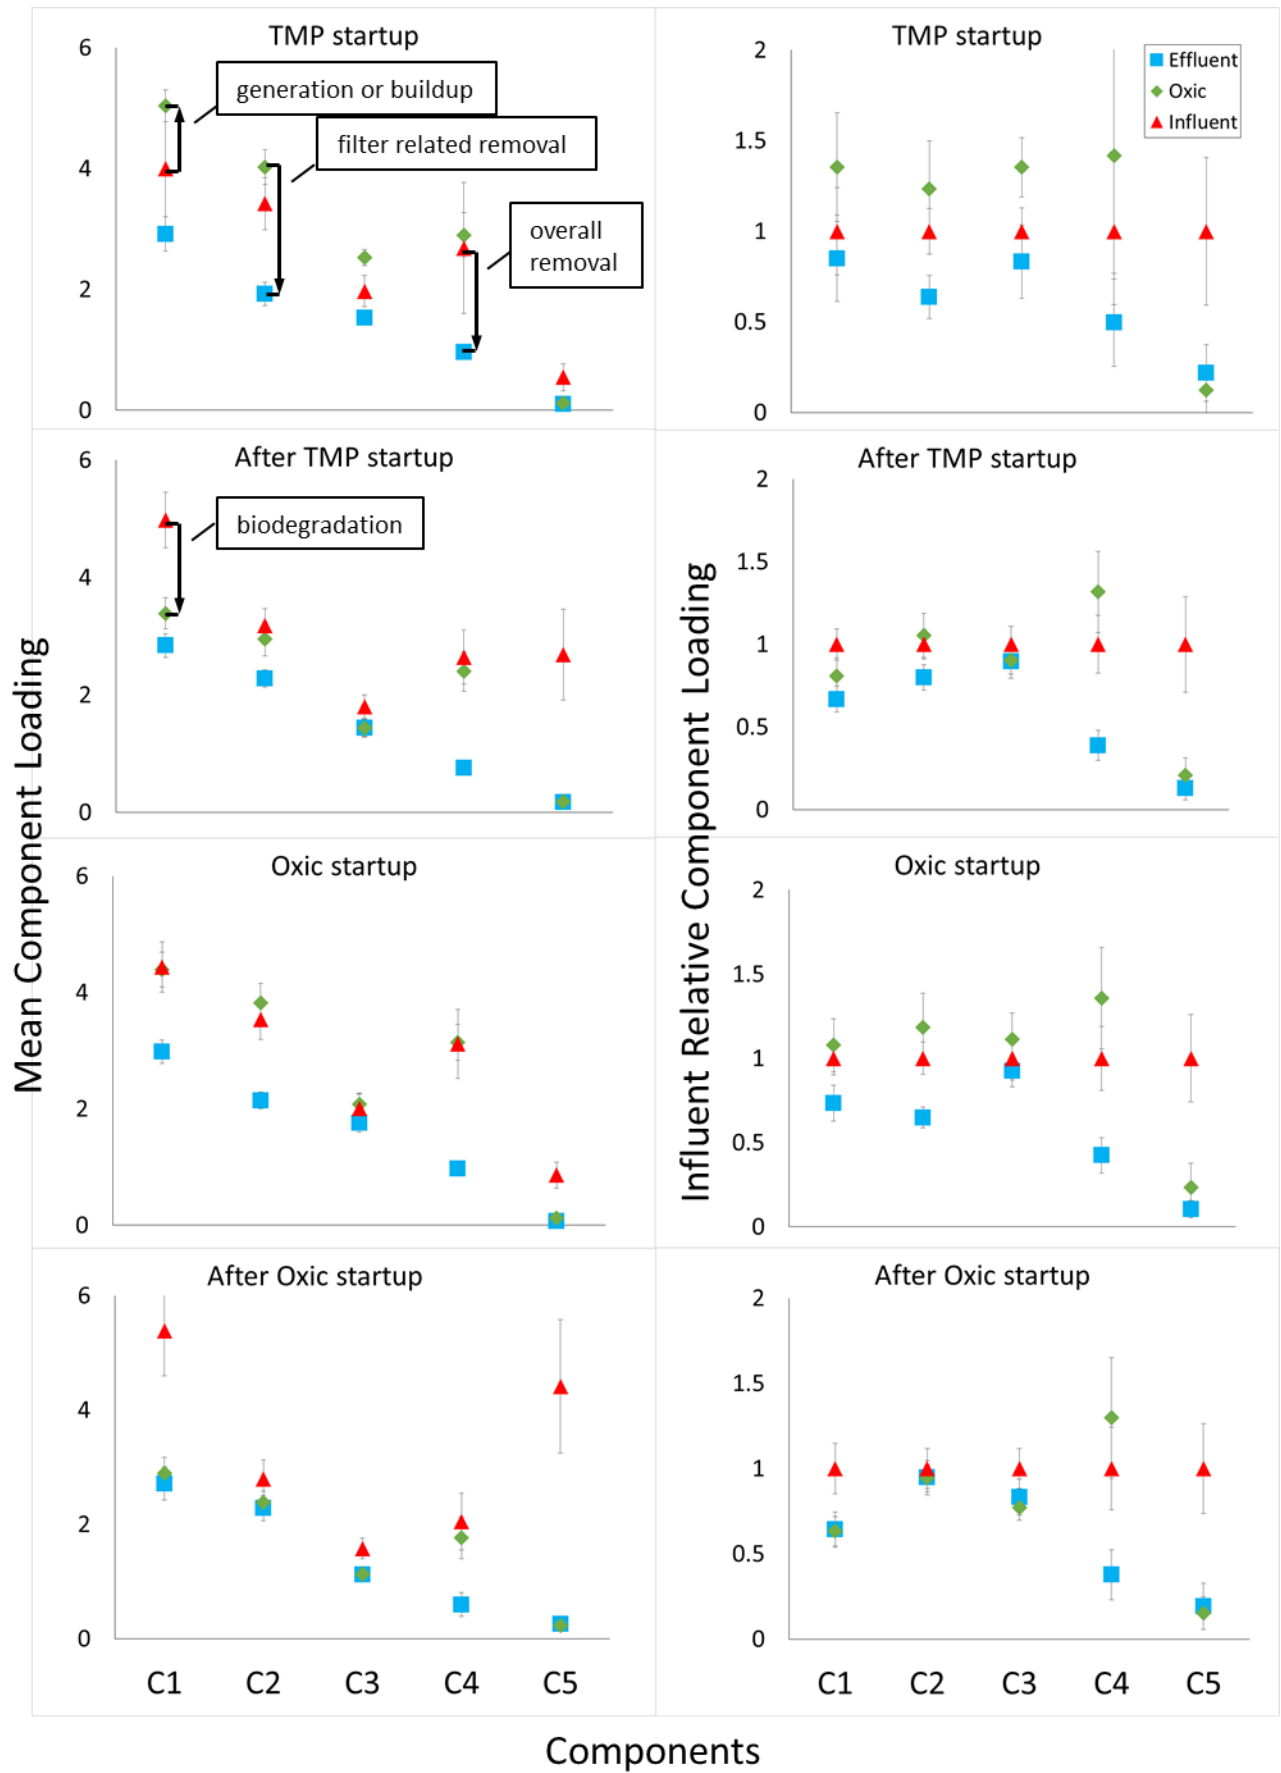

Figure 28 - Mean component loadings and mean relative component loadings for startup periods and post-startup. Mean component loadings for the given time period are on the left. Mean influent relative component loadings are on the right. A buildup of DOM is indicated where oxic tank loadings are greater than influent loadings. Biodegradation is indicated by a decrease in component loading from influent to oxic tank. Membrane related removal is indicated by a decrease in loading from the oxic tank to the effluent. The total removal for a given component is indicated by the difference in loading from the influent to effluent.

Figure 28 clearly shows an increase in some component loadings from the influent to the oxic tank. This is especially evident during the TMP startup phase. It is unusual to see components increase through the treatment process, but this has been reported previously (Hur et al., 2014; Saadi, Borisover, Armon, and Laor, 2006; Yang et al., 2014). This likely indicated a buildup of these components in the oxic tank rather than generation of these components. This could have been caused by retention of the components by the membrane coupled with low biodegradation of the material due to acclimation of the bacteria to the new environment. Additionally, **Figure 28** shows the same relationships as the composite loadings do in **Figure 22**. For composite loadings shown as percent distributions, refer to **Appendix A**: Supplementary figures.

Fluorescence Correlation to TOC Removal

Fluorescence peaks have been previously shown to relate to TOC concentrations in wastewater streams (Baker, 2002; Hudson et al., 2008; Reynolds et al., 2002; Vassel and Praet, 2002). This is a valuable information as organic matter poses several obstacles to efficient treatment of wastewater such as membrane fouling, increased oxidant demand, disinfection byproduct formation, and poor coagulation efficiency (Ishii and Boyer, 2012; Wang et al., 2009a; Yang et al., 2014). A fluorescence metric was found to correlate strongly to TOC removal

after the oxic tank startup phase for this MBR system. A linear regression was created between the ratio of humic components over protein like components from the influent and TOC removal between influent and effluent (**Figure 29**).

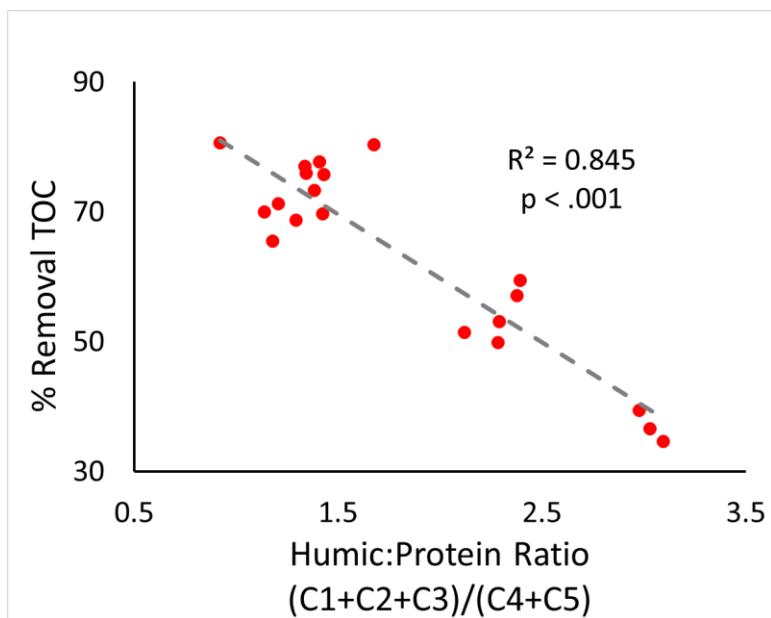

Figure 29 - Linear regression of humic:protein ratio to % removal of TOC

The humic:protein ratio has been developed by (Kulkarni et al., 2016) for determination of arsenic mobilization in groundwater in Bangladesh, however the ratio is also shown to be meaningful in this context. The more protein like character the DOM in the influent had, the higher the percent removal of TOC. This is expected as protein like fluorescent components were highly removed throughout MBR operation (**Figure 22**).

It is desirable that single wavelength peaks could be used to replace the need of developing a PARAFAC model, so the ratio of peak M (ex 312nm/ em 450nm) to a peak corresponding to C5 (ex 275nm/ em 360nm) was evaluated. **Figure 30** shows the regression between this peak ratio and percent removal TOC.

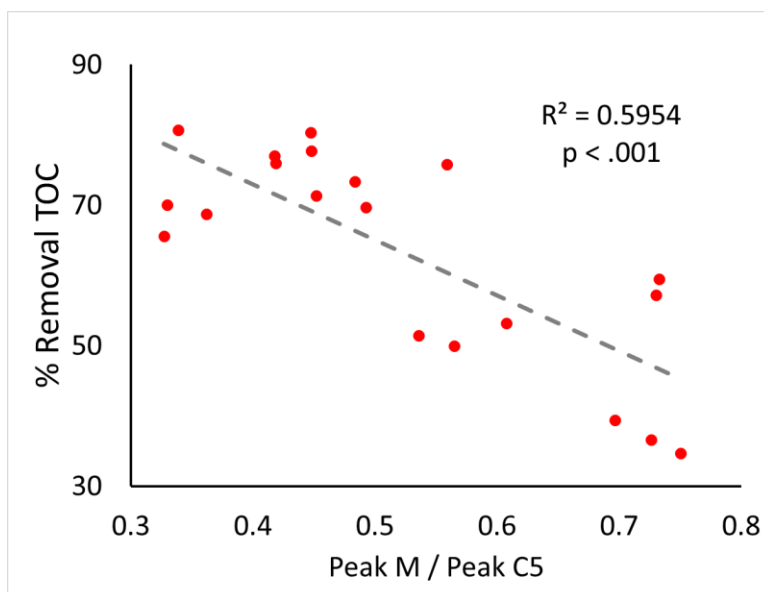

Figure 30 - Linear regression of peak M/peak at C5 to % removal of TOC

The peak M to peak at C5 ratio is similar to the humic:protein ratio in that it is a ratio of fluorescence related to humic-like material to that of protein-like material. The peak M to peak at C5 ratio does not show as strong of a correlation to TOC removal as the humic:protein ratio, but this ratio is far easier to obtain. The value of this ratio is in its simplicity as an indicator of protein-like character in the DOM.

Contamination Detection

Much work has been done in the development of fluorescence spectroscopy as a means for contamination detection in water treatment systems. These studies have elaborated on the strengths and weaknesses of fluorescence (Hambly et al., 2012; Henderson et al., 2009; Hudson et al., 2008), and also on the possible detection limits of this technique (Hambly et al., 2010; Stedmon et al., 2011). These prior detection limit studies have focused on drinking water systems. This study applies contamination detection methods in a water reuse scenario, where

treated water is much closer in quality to untreated water than in drinking water scenarios. This is to determine if fluorescence based monitoring is useful in these scenarios.

Upon analysis, it was determined that the single effluent and oxic tank samples used to create the standard curve were of unusual water quality. Most notably, the tryptophan-like C4 component loading in the effluent sample used in these dilutions was calculated to be 0 RU. The average C4 component loading for all other effluent samples is 2.95 RU. This seemed to indicate that the effluent sample used was an outlier and therefore, the detection limit determined via this single sample standard curve cannot be considered to apply to the system.

These series of dilutions do have some value, however. They may be used to determine the variability intrinsic to the standard dilution method and to compare the precision of the Total Model vs the Effluent Model. The detection limits of the two models applied to the dilution series is shown in **Figure 31**. From analyzing this data, the ratio between tryptophan C4 and humic-like C3 showed to have the greatest response to oxic tank carbon addition. This reflects the large difference between the loadings of C4 in the oxic tank and effluent, making the C4 loading a good indicator of contamination. C3 was chosen as a reference because it showed no significant difference between oxic tank and effluent.

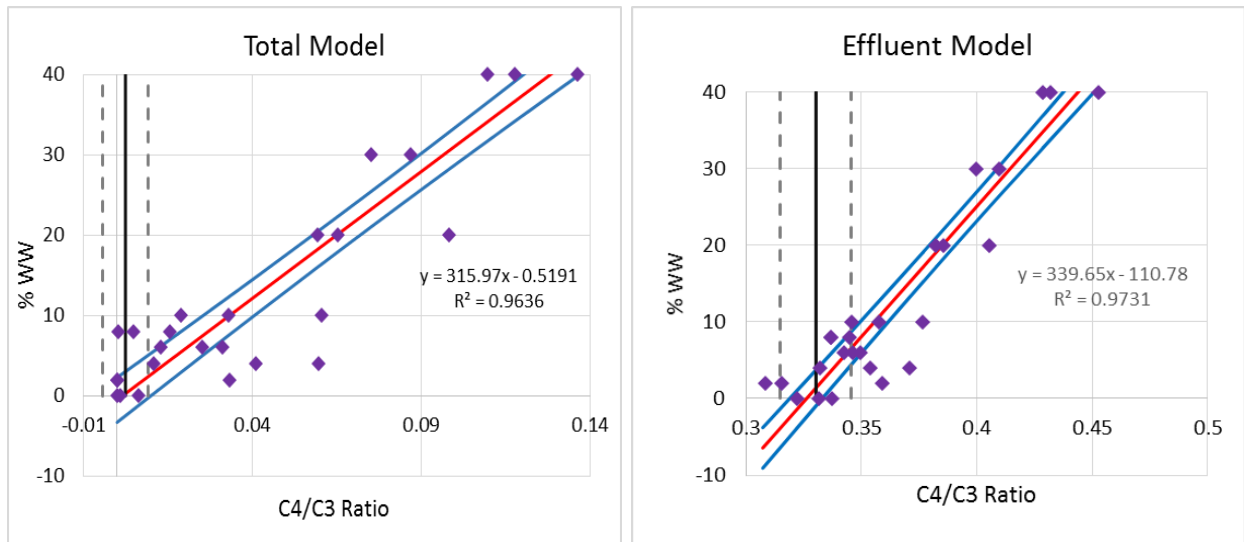

Figure 31 – Comparison of the detection limit of the Total Model and Effluent Model. Red and blue lines are the linear regression of the single sample dilution series and 95% CI of the regression, respectively. The black vertical line and gray hashed lines are the mean C4/C3 Ratio of the effluent sample and 2 standard deviations from the mean, respectively. Purple diamonds are the dilution series used to create the plots.

The regression line of the standard dilution series is shown in red. The linear regression for this series of dilutions shows very high R^2 values, similar to (Stedmon et al., 2011). The R^2 values given are for the full range of the dilutions, which include a triplicate measurement at the 100% oxic tank sample level. This sample is not shown in figure for clarity near the detection limit. Without the inclusion of this extreme sample, the R^2 for the Total Model and Effluent Model dilution series are .81 and .86, respectively. The blue lines in **Figure 31** are 95% confidence intervals of the regression. That is, if the experiments were to be repeated with an infinite number random samples from the same source, there is a 95% probability that the best fit line would fall within this interval. The confidence interval for the regression was applied in order to determine a measure of the uncertainty of this estimate. The regression lines were compared to the mean C4/C3 ratio taken from the triplicate measurements of the pure effluent

sample used in the dilution series. Two standard deviations from this mean are shown by gray vertical lines.

The detection limit is determined where the regression lines exceed two standard deviations from the mean effluent value. This range of percent wastewater values are the range in which there is a 95% probability that the true detection limit of the C4/C3 ratio lies. Based on the detection limits determined in this ideal case, the Total Model shows lower detection limits than the model based solely on the effluent.

To find a detection limit that was valid for this system, these detection limit methods were applied to the series of dilutions created using effluent and oxic tank sample pairs. In order to account for the variations in carbon concentration between the samples selected, the linear regressions were run between TOC (mg C/L) and the fluorescence component to be analyzed, rather than percent wastewater like the previous regressions. Again, the ratio between the tryptophan-like C4 and the humic-like C3 components showed the best response to the amount of oxic tank TOC added (**Figure 32**).

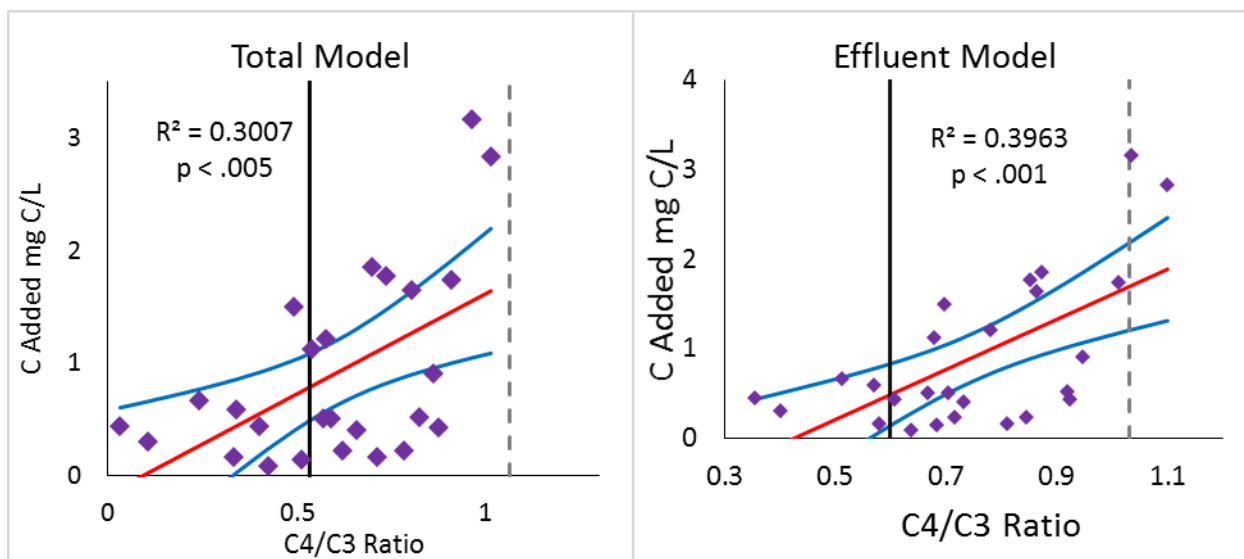

Figure 32 - Detection limit regression of the Total Model and Effluent Model using real samples from the oxalic tank and effluent. Red and blue lines are the linear regression of the single sample dilution series and 95% CI of the regression, respectively. The black vertical line and gray hashed lines are the mean C4/C3 Ratios of the pure effluent samples and two standard deviations from the means, respectively. Purple diamonds are the dilution series used to create the plots.

When using a variety of samples, the Effluent Model yielded the lowest detection limit. The Total Model response was similar to that of the Effluent Model, but the standard deviation of the average C4/C3 Ratio in the effluent was larger using the Total Model. This reflects the improved fit of the model using samples taken only from the effluent. For the Total Model, two standard deviations from the mean was outside the range of the standard dilution curve and no detection limit was determined. Using the C4/C3 Ratio of the Effluent Model yielded a mean detection limit of 1.70 ± 0.49 mg C/L from the oxalic tank. This amounts to ~31% of the average TOC of the treated effluent.

PARAFAC component loadings require a large sample dataset and are labor intensive to acquire. For this reason they do not lend themselves to online monitoring. Fortunately, single wavelength pairs have been shown to correlate strongly to PARAFAC component loadings

(Murphy et al., 2011; Yu et al., 2015). Single wavelength pairs were selected that monitor wavelengths in the same region as tryptophan-like C4 and humic-like C3. These wavelengths correspond to peaks T and C, respectively. Also, in the case of a single wavelength pair, peak B was shown to have the largest response (**Figure 33**).

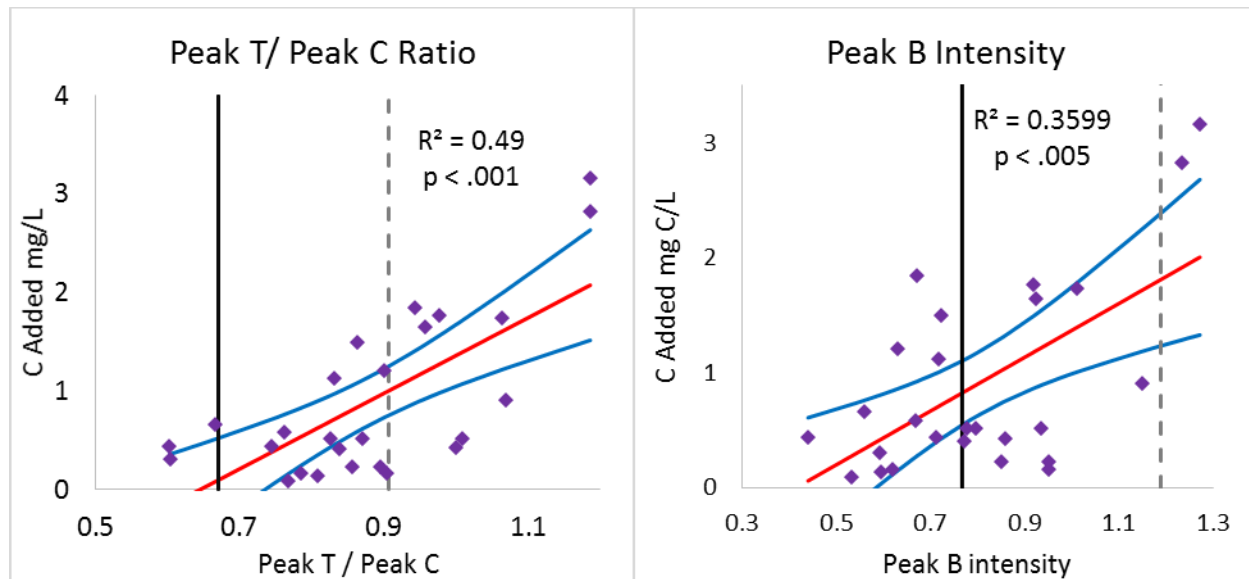

Figure 33 - Detection limit regressions using wavelength pairs identified from PARAFAC. The black vertical lines are mean peak T to peak C ratio and peak b intensities. Gray hashed lines are two standard deviations from these means. Purple diamonds are the dilution series used to create the plots.

Peak T / Peak C ratio yielded a mean detection limit of 0.99 ± 0.25 mg C/L and examining only peak B yielded a mean detection limit of 1.72 ± 0.53 mg C/L. The detection limit using a single wavelength was equal to that of using the PARAFAC components and the ratio of peaks showed even greater detection limits. This result is surprising, yet it has been reported that peak picking could have the advantage of being minimally affected by shifts in peak location compared to PARAFAC loadings (Yu et al., 2015). This is possibly the cause of the increase in sensitivity observed as the oxic tank conditions and effluent quality of the system under

consideration has been shown to be variable. It is for this reason that (Yu et al., 2015) recommends only using PARAFAC for monitoring contamination from a source that has components or peaks that are not normally present in the monitored water.

It should also be considered that while the fluorescence peak related methods yielded lower detection limits, the Pearson's R of these regressions was much lower than those of the PARAFAC based techniques. Therefore, the reliability of these relationships is in question. In this area, the PARAFAC based methods can provide greater confidence in the determined detection limit.

Twenty six pairs of samples were used in this study which had the effect of drastically lowering the R^2 of the regression of this dilution series compared to the single sample dilution series. This is due to the increased variability in the sample set. This is the difference between using a single sample to create a series of dilutions, as done by Stedmon et al. (2011), and using multiple samples. As shown above, the conditions in the oxic tank and the quality of the effluent change over time and even show variation between samples collected at the same time. Additionally, as was seen from the dilution experiment run with a single pair of samples, the single sample pair may not be representative of the system. This result indicates that the variability of the water treatment system over time should be taken into account when determining contamination detection limits and multiple samples should be used whenever possible. Future contamination detection limit studies should be careful to consider the variability of the system being studied.

Fluorescence as a Monitoring Technique for Wastewater Treatment

Fluorescence was shown to be an effective tool to monitor the removal of carbon throughout the waste stream for a full scale MBR (**Figure 22**) and to correlate to TOC removal for a given source of waste (**Figure 29**). While fluorescence did relate to the safety of reclaimed water in that untreated oxic tank water was detectable in the effluent of the MBR system (**Figure 32**), the fluorescence parameters did not correlate directly to *Escherichia coli* or total coliform measurements. These bacteria are used as indicator species for the contamination of a water source by fecal material.

The relationships between fluorescence parameters and coliform measurements were investigated and are shown in **Appendix A** at **Total coliforms** and **E. Coli**. Unfortunately, no significant correlations were found between these coliform measurements and any fluorescence measurement. This may be related to the very low amounts of coliforms in the effluent of the MBR system. The majority of the coliform tests returned 0 MPN total coliforms and 0 *E. coli*. Perhaps at high coliform loadings, a direct relationship could develop. It is also important to consider that coliforms and *E. coli* make up only a portion of the bacteria present in wastewater. Efforts to quantify other bacterial counts may have been more fruitful. This is not to say that fluorescence techniques do not offer useful information about water treatment, but simply that they do not directly measure these pathogens.

Chapter 5 - Conclusions

The world's water resources are under pressure and increasingly so (Millennium Ecosystem Assessment, 2005). Failure to respond to these pressures results in increased water security risks. As much as 80% of the world's population has been reported to be in areas of high water security risk due to a convergence of factors, such as watershed disturbance, pollution, water resource development and biotic factors (Voeroesmary et al., 2010).

Communities in developed nations are highly shielded from the impacts of diminished water security by the ability to offset risk through investments in infrastructure (Voeroesmary et al., 2010), yet in the U.S. this infrastructure is rapidly aging and reaching the end of designed lifetimes. For example, the American Water Works Association's report, *Buried No Longer: Confronting America's Water Infrastructure Challenge*, predicts that restoring and expanding the existing drinking water infrastructure in the U.S. will cost at least 1 trillion USD over the next 25 years (Raucher et al., 2012). These costs, coupled with government restrictions on water use provide strong incentive for the development and implementation of water reuse technologies at decentralized locations near consumers (Li et al., 2011).

With the implementation of water reuse systems, there comes increased risk and an increase in perceived risk by the public (Hambly et al., 2012; Henderson et al., 2009). This risk can be mitigated by rapid and sensitive water treatment monitoring technologies. Fluorescence spectroscopy has shown much promise in this regard due to its sensitivity, selectivity, and ability to be placed online in water treatment streams (Hambly et al., 2010; Henderson et al., 2009).

The goal of the present study was to further evaluate the effectiveness of fluorescence spectroscopy as a water quality monitoring technique. To this end, a full scale MBR system treating wastewater from a military barracks in Fort Riley, KS was monitored using fluorescence

spectroscopy along with other water quality measurements over a period of three months in 2016. Fluorescence was employed online to the effluent of the system and grab samples were collected periodically for the generation of full EEMs. From these EEMs, two PARAFAC models were created for the comparison of PARAFAC, EEM analysis, and online fluorescence as monitoring techniques.

From the examination of the online data and grab samples, two startup periods were identified instead of a typical single startup period. During the first 60 days of the study, the TMP increased steadily and then levelled off. This change in pressure across the membrane reflected the development of a biofilm on the membrane surface. During the first 91 days, the nitrogen and phosphorus levels of the oxic tank increased and then levelled off. Additionally, as the nutrient levels began to stabilize the biodegradation of DOM in the oxic tank began to increase. Both of these startup phases showed value in predicting trends over time in fluorescence components and the removal of those components.

From the grab samples, a series of dilutions were made to simulate contamination in the effluent from the oxic tank. A comparison of fluorescence related monitoring techniques showed that the most sensitive parameter for detecting effluent contamination was a ratio of the intensities of peak T / peak C, which yielded a detection limit of 0.99 ± 0.25 mg C/L. It is possible that the peak T / peak C ratio correlated more closely to the amount of oxic tank in the diluted sample because the peaks were less susceptible to slight variations in peak location, and therefore more able to reflect the true signal, rather than noise. The finding that a ratio of peaks showed greater sensitivity than a ratio of two component from a PARAFAC model has important implications for water reuse monitoring. The use of peak intensity data is much less time consuming and requires less processing after data collection.

Also, a simple parameter was shown to relate to treatment efficacy of the studied MBR system. The ratio of the influent humic-like components to protein-like components was shown to correlate well with TOC removal ($R^2 = .845$, $p < .001$). Due to the time consuming nature of PARAFAC and the necessity of a large number of samples to create the PARAFAC model, single peaks were evaluated that monitored fluorescence intensity at wavelengths correlated to a humic-like component (C1) and a protein-like component (C5). The ratio of these peaks showed low correlation, but was still shown to have a significant relationship with TOC removal ($R^2 = .595$, $p < .001$). The more protein-like character the DOM had in this system, the greater the TOC removal the system was able to accomplish.

Fluorescence was shown to be useful for treatment monitoring over time, contamination detection, and to relate to TOC removal, but was not shown to relate directly to the presence of water borne pathogens. In addition to verifying the two phase startup period identified in this research, future needs in the evaluation of fluorescence spectroscopy in water treatment monitoring include: a greater understanding of the effects of dynamic influent quality on wastewater treatment and how this influences fluorescence based monitoring techniques, broadening the types of systems for which fluorescence based contamination detection limits have been investigated, and further investigation of the sources of temporal variation in treatment efficacy in MBR systems. While much work in this area has been accomplished, there is still need for improved water treatment monitoring technologies.
