INTRODUCTION

The development of high yielding populations of grain sorghum, superior to those now available, is an important goal in grain sorghum breeding. However, yield and most other traits that breeders are interested in are not simply inherited in a Mendelian fashion. Therefore, progress in breeding programs may be considered as a function of interrelationships of genetic and nongenetic variations in those important traits.

Major yield components of grain sorghum are kernel number and kernel weight. Little progress has been made in the exploration and explanation of the associations among these complexly inherited traits and other important agronomic traits.

A knowledge of the interrelationships among agronomic traits is of value because it provides a basis for the development of selection indexes for the simultaneous improvement of traits, for avoiding selection of undesirable traits, and for efficient selection of traits with low heritabilities. Since grain yield has a low heritability in grain sorghum, it is of great value to know the traits which are highly associated with it to maintain a highly effective breeding program for high grain yielding capacity.

The purposes of this investigation were (1) To find if there is a correlation between stomatal number and yield, with detailed analysis and interpretation, (2) To find the relative importance of contributing factors toward yield by multiple regression analysis, (3) To estimate the interrelationships between kernel weight and kernel number per plant under 2 different plant spacings, specifically 6 and 12 inches within rows, and (4) To determine interrelationships between pairs of variables observed under 2 different plant spacings.

REVIEW OF LITERATURE

STOMATA

There is considerable diversity in stomatal density between species in regard to the variability within and between the leaves. Eckerson (1908) reported that in most leaves studied the stomata were fairly evenly distributed over the surface of the blade, but in some species the stomata were more numerous near the midrib than near the margin of the leaf. Peterson (1929) reported that in varieties of Rumex acetosa from different habitats that stomatal frequency varied little between the regions of the same lamina. Wicks (1935) found that in Amaryllidaceus, stomatal frequency increased from the base of the blade toward the apex and from the median line to the margin of the lamina. Yapp (1912) and Cowart (1936) reported that stomatal frequency was greater in the higher leaves of apple trees than in the lower leaves. Yapp (1912) also stated that transpiration rate through the smaller but more numerous stomata of the upper leaves was not much greater than that through the larger but fewer stomata of the lower leaves of Ulmaria palustris.

Smith (1941), using Phaseolus vulgaris, found that stomatal frequency within a leaf was the highest near the apex and the lowest near the midrib, and in different leaves it was apparently higher at the upper than at the lower levels of a plant. Smith also stated that there was a positive correlation between stomatal frequency and transpiration rate.

Hesketh (1963), working with castor beans (Ricinus communis), maize (Zea mays), tobacco (Nicotiana tabacum), red clover (Trifolium pratense), sugarcane (Saccharum officinarum), and sunflower (Helianthus annuus), reported that stomatal frequency and length were not related to maximum photosynthesis.

Freeland (1948) also found that stomatal frequency was not correlated with greater photosynthesis among the same species of several plants.

Roovaart and Fuller (1935) working with cereals explained the variation of stomatal frequency within a species was due to optimum conditions or below optimum conditions. A low frequency under optimum conditions is found because the epidermal cells are larger and hence there is greater distance between the stomata. Evidently, it follows that, the ratio of the number of stomata to that of epidermal cells remains about constant under all conditions.

Hunt and Christie (1969) working with leaves of bromegrass, found there were variations in stomatal numbers and lengths between plants of the same varieties. Those differences could also be detected with some degree of reliability by using a silicon impression technique.

Miller (1938) classified a large number of species and varieties of crop plants on the basis of stomatal characteristics and concluded that the number of stomata per unit area of leaf surface is within limits, specific for different varieties and species.

Dunn (1965) reported that the size of stomata in monocotyledons was much more consistent than in dicotyledons. However, he concluded that the frequency per unit area was a more reliable characteristic in both monocotyledons and dicotyledons with size of stomata being a fairly reliable characteristic in monocotyledons.

Birdsall and Neatby (1944) working with Triticum vulgare and other Triticum spp reported that there were significant differences among varieties and hybrid strains of spring wheat with respect to the length and frequency of stomata per unit area. A negative correlation was found between size and frequency of stomata both between species and between varieties within a species.

Yield was found to be significantly correlated with stomatal frequency, while the relation with stomatal size was negative. Differences in plants were found to have a bearing on stomatal characteristics among varieties, small plants had small stomata and relatively large number per unit area, larger plants had larger stomata and fewer per unit area.

Eckerson (1908) and Muenscher (1915) demonstrated that there is an inverse relationship between frequency and size of stomata. Dobrenz, Wright, Humphrey, Massingale, and Kneebone (1969) working with Blue Panicgrass (Panicum antidotale Retz), reported that leaves adjacent to the inflorescence had significantly lower stomatal density than those at the middle and base of the culm. No difference was found among stomatal densities at the three positions on a leaf; tip, middle, and base. A nonsignificant correlation between water-use efficiency and stomatal density was also reported.

Teare (1969), from research with wheat (Triticum vulgare) found that stomates varied from 9,000 to 16,000 stomates per cm^2 for flag leaves between varieties and species. Differences were also found between leaves on the same plant. On the average it was found that on the flag leaf there was an average of 12,200 stomates/ cm^2 compared with 10,300 stomates/ cm^2 on the first leaf below the flag leaf. The second and third leaves are similar to the first leaf. Originally the tip, mid section, and base of the leaf were sampled, however, the mid section proved to be the most reliable.

INTERRELATIONSHIPS AMONG AGRONOMIC CHARACTERS

Interrelations among agronomic characters in grain sorghum (Sorghum bicolor Moench) has been investigated by several authors. Of the primary components of yield in grain sorghum, weight of seeds, number of seeds per

head, and number of heads per unit areas, it was concluded that seeds per head was the most important (Nielaus 1966, Quinby 1963). Kirby and Atkins (1968) studied the inter-character correlations among 24 F_1 grain sorghum hybrids and found grain yield was positively and significantly correlated only with seeds per head. Dalton (1967) after testing F_1 hybrids with a wide range of maturities concluded that a positive regression existed between higher yields and later maturity.

Liang (1969) estimated phenotypic and genotypic correlations among characters for 15 F_1 hybrids (Sorghum vulgare Pers) and found that grain yield was positively and significantly correlated with half bloom date but the correlation with kernel weight was low. Liang, Overley, and Casady (1965) in a later investigation with pure lines and segregating populations of grain sorghum (Sorghum bicolor Moench), found that grain yield was positively and significantly correlated with head weight, kernel number, half bloom date, and leaf number. An inverse relationship between kernel weight and kernel number was also found in this study. Head weight and half bloom date were considered the best indicators for yield.

Niehaus and Pickett (1966) using 28 F_1 hybrids of grain sorghum (Sorghum vulgare Pers) determined that grain yield was positively and highly significantly correlated with seeds per head, plant height, half bloom date, number of leaves, and threshing percentage. In the F_1 generation number of seeds per head had the largest direct effect on yield. Although height was highly correlated with yield, its influence was indirect and was primarily through number of seeds per head.

Rao et al. (1965) emphasized the importance of the study of the association of yield components with yield since the component characters which have

decisive roles in influencing yield may be used for additional indices for selection from breeding material. They listed 6 characters as the grain sorghum yield components, 1) number of tillers per plant, 2) length of panicle, 3) weight of ear-head, 4) days to maturity, 5) threshing percentage, and 6) test weight. In the study of correlations between the yield components and the final yield, they reported that weight of ear-head, days to maturity, and test weight were highly and significantly correlated. But lengths of panicle were negatively correlated. Number of tillers and threshing percentage were not significantly correlated.

Sieglinger (1936) using different varieties of grain sorghum (Sorghum bicolor Moench) reported that numbers of leaves was positively and significantly correlated with half bloom date, diameter of stalk, and plant height. Casady, Hadley, Freeman, and Javier (1965) found that plant height was positively and significantly correlated with grain yield.

Blum (1967) found that with higher soil fertility the 1000 grain weight tends to increase along with the number of branches per whorl, and the number of grains per branch. Low plant competition, rows 30 inches wide, increased the number of whorls per panicle and the number of grains per branch, compared with high plant competition or rows 50 inches wide. These factors contributed to a significant increase in the number and weight of grains per panicle. There was a negative correlation, which increased as the number of grains per panicle increased, between the weight of grain and number of grains per branch. Martin (1928) reported that within a given variety of grain sorghum (Sorghum vulgare Pers), that height of plant is highly correlated with grain yield and that conditions which favor elongation of the internodes of the sorghum stalk also favor an increase in the number and size of seeds per head.

Thus, environmental conditions favorable for greater plant height also favored greater yields per acre and greater seed size.

Atkins, Reich, Beil, and Kirby (1968) found an association between panicle weight and threshed grain weight in grain sorghum. However, they concluded that for most studies the separation of the grain from the panicle was a necessary procedure for accurate yield estimations.

Adams (1967), using field beans (Phaseolus vulgaris), found that negative correlations among yield components are widespread among the major crop plants, particularly under various kinds of environmental stress and these correlations are attributable to developmental induced relationships rather than genetically inherited.

MATERIALS AND METHODS

FIELD EXPERIMENTS

Thirty-six F_1 hybrid lines of grain sorghum were planted in fall-plowed, weed-free seedbeds in 1969 and 1970. They were: WAC 690-A; T.E. Mucho; Weather Master 76-Y; RS 702; RS 633; RS 626; RS 625; Richardson 404 SR; P.U. 685; Pioneer 820; Pioneer 845; P.U. 634; Pioneer 846; Pioneer 828; NK 222A; Excel 707; Frontier 413; Excel 505; NK 222G; Dekalb F-64; NC-T-700; Asgrow Flare; NK 275; Horizon 80; Dekalb E-57; Asgrow Jumbo C; Dekalb C-48a; Advance 91; Dekalb C-44c; Advance 76; Acco R2020; Acco R109; Weather Master G-61y; and T.E. Grain Master A.

Two locations were used in each of the 2 years. Kansas State University Agronomy Farm at Manhattan (1969) and Ashland (1970), and the Experiment Field at Powhattan, Kansas (1969 and 1970). The F_1 hybrids of grain sorghum were planted in rows spaced 91 cm (36 inches) apart in both experiments in 1969 and Powhattan in 1970, but in 1970 at Ashland the row spacing was 76 cm (30 inches). The plants within the rows were thinned to 15 cm (6 inches) apart in the first experiment and thinned to 30 cm (12 inches) apart in the second experiment. This same row spacing and plant spacing were used in both years at both locations. A cone type hand planter was used to do all of the planting in 1969, and all but 7 hybrids in 1970, where the amount of seeds was limiting and hand planting was necessary.

Grain sorghum hybrids at Manhattan were planted on June 16, 1969 for the first experiment and on June 25, 1969 for the second experiment. Those plots were planted in a alluvial silty clay loam soil, with a previous crop of wheat. In 1970, the grain sorghum at Ashland was planted on June 17 for the

first experiment and on June 18 for the second experiment on very similar soil types with soybeans as the previous crop.

Soil moisture condition at planting time was good at both Manhattan and Ashland in 1969 and 1970, respectively. Precipitation for the first 60 days after planting at Manhattan in 1969 totaled almost 12 inches. While at Ashland in 1970 the precipitation for the first 60 days after planting totaled only 3 inches. The rain was fairly well distributed in 1969, but in 1970 rain was negligible the first 8 weeks after planting. High temperatures accompanied by hot, dry winds put the sorghum under drought stress during the months of June, July, and August.

The experiments at Powhattan were planted in a clay loam soil, where the previous crops were wheat and soybeans, respectively. Dates of planting for 1969 and 1970 were June 4 and June 23, respectively.

Good soil moisture conditions existed at Powhattan both years during planting, with 1970 being the drier of the two years. April of 1969 had almost 2 inches of rain above normal and May had 1 inch above normal. April and May of 1970 both had below normal rain fall. The precipitation for the first 60 days after planting in 1969 totaled 9.93 inches, while in 1970 it totaled only 3.33 inches. Here, as in Ashland, hot, dry winds put the sorghum under a drought stress condition.

Mechanical weed control was used at Powhattan in 1969. This consisted of rotary hoeing the sorghum when it was about 2 inches high and several sweep cultivations during the early part of the growing season. Weed control at Manhattan was made by herbicide spray and rotary hoeing and three mechanical cultivations. Some hand hoeing was also necessary. In 1969, atrazine was applied at the rate of 1.5 pounds of active ingredient per acre to the experiment at Manhattan, where weeds presented a special problem.

In 1970, the seedbed at Powhattan was treated with a preplant herbicide which all but eliminated further measures of weed control, except some hand hoeing. Weeds were not a problem at Ashland in 1970 because of a preplant herbicide spray. Cultivation and some hand hoeing were adequate for proper weed control.

A complete randomized block design with 2 replications was used in this experiment. Each plot of the first experiment at each location consisted of 3 rows 22 feet long, of which only 20 feet of the center row was collected for data. The second experiment consisted of 3 rows 44 feet long with plants 12 inches apart of which only 40 feet of the center row were used in data measurements.

Agronomic traits studied in this experiment were:

Stomatal numbers were obtained by the use of a microscope at the magnification of 7.5X by 20X and counted directly. Three areas of the 6th leaf (flag leaf being counted as number one) were used; base, middle, and tip with 5 readings from each area. The 6th leaf was chosen for this study because in a preliminary study the stomatal number of the 6th leaf was found to be the most highly correlated to the number per unit area of the entire leaf surface of the plant. Only the stomata on the lower surface of the leaves were counted because of the position of the stomata and ease of counting.

A 20-foot section of each plot was harvested for yield in the first experiment, and 40-foot for the second experiment. Heads were removed by hand with a linoleum knife and later threshed with a small-plot thresher. The amount of grain per harvested area was recorded and a moisture meter reading taken and the grain was adjusted to 10% for net yield.

Half bloom date was recorded as the number of days from seeding to anthesis of 50% of the plants in each testing plot.

Head number was determined by counting the number of harvestable heads in the 20 foot and 40 foot section to be harvested.

Peduncle diameter was measured 2.5 cm (1 inch) below the panicle base with micrometer calipers after anthesis of the entire head.

Plant height was measured in centimeters from ground level to the collar of the flag leaf for 20 plants in each plot. The average height was then used for each testing plot.

Total leaf number was recorded after marking every fifth leaf starting with the coleoptile. The total number of leaves was recorded after anthesis.

Kernel number per plant was calculated by counting the number of seeds in a 25 gram sample with a electronic seed counter and adjusting this to 10% moisture level.

Kernel weight per 1000 seeds was arrived at by taking the number of seeds per 25 grams of each plot and converting it to a 1000 seed level, at 10% moisture.

Leaf area in this experiment was the average leaf area of the fourth and fifth leaves (flag leaf as number one). The leaf area was determined by measuring the length and width and multiplying by a factor of .75. The fourth and fifth leaves were found to be the most highly correlated pair of leaves in relation to the total leaf area in a preliminary study. The measurements were taken after the appearance of the flag leaf and leaf growth had stopped.

STATISTICAL ANALYSIS

Statistical analysis were made on a plot means according to the methods outlined by Fryer (1966) for multiple linear regression analysis. In some statistical studies, it is advantageous to consider 2 or more types of numerical measurements simultaneously, because they may be related to the dependent variable and related to each other. For example, in this study, it was desired to see what degree of relationship existed between the dependent variable, grain yield, and the independent variables, plant height, kernel number, kernel weight, leaf number, leaf area, peduncle diameter, stomate number, head number, and half bloom date.

The multiple regression model situation assuming that "y" is linearly related to 2 or more X's or X_1, \dots, X_s , is:

$$Y = \beta_0 + B_1 (X_1 - \mu_1) \dots B_s (X_s - \mu_s) + E$$

where:

Y is the dependent variable

β_0 is a constant

B_1 is the slope of the regression plane in the X_1 direction

X_1 is the first independent variable

μ_1 is the mean of X_s

B_s is the slope of the regression plane in the X_s direction

X_s is the "s" independent variable

μ_s is the mean of X_s

E is the amount by which the point (X_1, X_s, Y_{ijk}) is above or below the regression surface

The coefficient of determination, R^2 , was estimated in order to evaluate the relationship of the 9 independent variables with the dependent variable. The amount of contribution of each variable to the R^2 was also calculated.

R^2 is the fraction of the total sum of squares of Y attributable to the independent variables. In other words, R^2 explains what portion of the observed variability among the Y's, as measured by $\sum(y^2)$, is assignable to multiple linear regression on the included variables. If the R^2 is large, most of the variation in "Y" is explained by the variables already included. If the R^2 is low, the variation in "Y" is mostly unexplained due to random variation or other important variables not included in the regression.

RESULTS AND DISCUSSION

STOMATAL NUMBERS AND YIELD

The stomata are openings in the epidermis bounded by two specialized epidermal cells (guard cells) which by changes in shape bring about the opening and closure of the aperture. The stomata, therefore, control the in-flow and out-flow of gases to the leaves of plants. A greater number of stomata would allow a entrance of more CO_2 and thus increase the overall yield of the plant. This is an oversimplification, as many factors could influence this action, such as size of stomata, and environmental conditions. However, this investigation was designed to see if a correlation does exist between stomata numbers and yield. The correlation coefficients between stomata numbers and grain yield are given in Table 1.

In 1969, 3 different techniques were utilized to calculate stomatal density. The first method gave equal weight to the tip, middle, and base of the leaf, with 5 readings from each. This number was then adjusted to stomates per mm^2 and multiplied by the leaf number and leaf area for total stomata number. The second method only utilized the center portion of the leaf which was multiplied by leaf number and leaf area. The third method included only stomate number per mm^2 without any use of leaf number or leaf area. Simple correlation coefficients were then computed between these 3 outcomes and grain yield. However, none of these 3 investigations gave significant or near significant correlation coefficients.

The highest correlation indicated that only 3.00% of the variation in grain yield could be accounted for by stomata number. This leads to two conclusions (1) There was no correlation between stomate number and grain yield, or (2) Error overshadowed the outcome and produced no association where one does exist.

Table 1. Simple correlation coefficients for stomate numbers vs grain yield for 2 locations, 2 years, and for 2 different plant spacings of grain sorghum.

Variable:	Manhattan		Ashland		Powhattan		
	1969	12-inch	1970	12-inch	1969	12-inch	
Grain yield with:	6-inch	12-inch	6-inch	12-inch	6-inch	12-inch	
Total stomate number	.088	-.044	-.138	.141	.089	.174	-.345
Stomate (center portion only)	.103	-.131	-.192	.148	.061	.128	-.386
Stomate density	.025	-.016	-.132	.066	-.009	-.127	-.275

It is reasonable that a correlation does exist because it has been shown to exist in other monocotyledon plants. Teare (1969) from an investigation with wheat (Triticum vulgare) concluded that for a high yielding variety, 10,500 stomates per cm^2 was required for the flag leaf.

It was found in grain sorghum that stomata number increased from the base of the leaf to the tip in all hybrids. The size of the stomata also changed and seemed to become larger as their position neared the tip. Numbers did not increase significantly from the midrib to the edge. However, size did appear to be smaller, nearer the midrib.

Error in this investigation could have been included by many factors. Of these the most important ones are: 1) Differences in size of stomata, 2) Exact position on leaf where the three samples were collected, (tip, middle, and base) where differing lengths of leaves of different hybrids caused difficulty, 3) Closeness to midrib, with different widths of hybrids, 4) Error in the actual counting of stomata under the microscope, and 5) The choice of leaf from which to sample. The 6th leaf was chosen for sampling because in a preliminary study using RS 610, it exhibited the highest correlation for stomate number to the total stomate number of the plant. The samples from the 6th leaf showed the highest correlation to the total stomate number of the plant. This variety has approximately 20 to 21 leaves per plant. However, in hybrids of this investigation leaf number varied from 18 to 22, and the 6th leaf might not have been the best choice in all cases.

Generally, the association, low as it was, did increase from the 6 inch spacing to the 12 inch spacing, however, not enough increase was noted to draw any substantial conclusions.

MULTIPLE LINEAR REGRESSION

The relative magnitudes of several yield components contributing to grain yield were computed by R^2 . R^2 is a measure of the goodness of fit of regression from a group of independent variables. Table 2 shows the multiple linear regression of the dependent variable grain yield and the other 9 independent variables.

The coefficients of determinations, R^2 , were very high and consistent in all of the cases investigated. They were all of the magnitude of 0.943 to 0.995, which indicate that most of the variation in grain yield could be explained by the independent traits included in the investigation. However, considering both spacings, locations, and years almost all of the R^2 was attributable to 2 variables, specifically kernel number per plant and kernel weight. With kernel number contributing approximately twice that of kernel weight. Contributions by the other 7 independent variables, head number, leaf number, half bloom date, peduncle diameter, plant height, leaf area, and stomata number, were not significant.

STANDARD PARTIAL REGRESSION

Estimation of the standard partial regression coefficient provides a means of distinguishing magnitudes of single effects from complex associations. The standard partial regression coefficient also measures the relative importance of each causal factor, whereas correlation simply measures mutual association without regard to relative importance.

The obtained standard partial regression coefficients for both locations, spacings, and years are given in Table 3. In all cases investigated, the coefficients obtained for kernel number and kernel weight were high and

Table 2. Multiple linear regression of yield on 9 independent variables for 2 locations, 2 years with 2 different plant spacings of grain sorghum.

significant, with the other 7 agronomic traits contributing practically nothing. These results are identical with those of the multiple linear regression coefficient analysis.

INTERACTIONS AMONG KERNEL NUMBER, KERNEL WEIGHT, AND HEAD NUMBER

Since the interrelationships of kernel number, kernel weight, and head number are of a special case, these relationships will be discussed first with the remainder of the relationships following.

The interactions among kernel number, kernel weight, and head number are complex, as the amount of nutrients, etc. are increased (6 inch plant spacing to 12 inch), the association of kernel number with head number increases and the association between kernel number and kernel weight fluctuates but not in any specific pattern. In 3 of the 4 investigations kernel number was found to be negatively significantly correlated with kernel weight. Head number was found to be positively correlated with kernel number, but not significantly in all investigations. This would indicate that head number would be negatively correlated with kernel weight, but in these investigations this could not be substantiated. These interrelationships are shown in Diagram 1. Seeds per head is usually considered to be the most highly correlated with grain yield. However, in these investigations seeds per whole plant were measured instead of seeds per head. This would mean that if there was an association between head number and yield some of this relationship would be included in the correlation of kernel number with grain yield. These correlation coefficients are given in Table 4. At the 6 inch spacings the correlations of head number to grain yield are nearly zero, therefore, head number could not be contributing much toward the relationship of kernel number to grain yield. However, in

Diagram 1. Interrelationships of the main components of yield; kernel number per head, kernel weight, and head number.

the 12 inch investigations, head number is positive and significantly correlated with grain yield, therefore it is or could be contributing to the correlation of kernel number and grain yield. Head number could contribute to the relationship of kernel number per head with grain yield if the average kernel weight per seed is different in the tiller heads or between the harvested tiller heads and the main head.

At Powhattan in 1970 a positive and significant correlation was found between kernel number and kernel weight. This discrepancy from the other correlations could have been caused by climatic conditions; temperature, sub-soil moisture, or specific dates of rainfall, interacting with the developmental growth of the sorghum hybrids.

INTERRELATIONSHIPS AMONG TRAITS

Interrelationships among agronomic traits are of considerable value for planning and evaluating breeding programs. A knowledge of these interrelationships is valuable because it provides a basis for the development of selection indexes for the simultaneous improvement of traits, for avoiding selection of undesirable traits, and for efficient selection of traits with low heritabilities. Since grain yield has a low heritability in grain sorghum (Liang 1968), it is of great value to know the traits which are highly associated with it to maintain a highly effective breeding program for grain yielding capacity.

Simple correlation coefficients among traits were computed (Tables 5,6,7, and 8) for all pairs of traits for the 36 F_1 hybrids for 2 years, 2 locations, with 2 different plant spacings. Associations between these traits were variable but did show some significant interactions.

Upper diagonal is the data from the 12 inch spacing and the lower diagonal is the data from the 6 inch spacing.

Grain yield was highly associated with kernel number consistently in all of the investigations, with kernel weight being associated frequently in both 6 and 12 inch spacings. In these 12 inch spacing a killing frost caught the plants before full maturity, thus causing a decrease in grain yield, which should not have been shown if frost had not stopped their development.

Half bloom date was found to be negatively correlated with kernel number at the 12 inch spacings, but slightly positively correlated at the 6 inch spacings. This is reasonable, because if the plants are crowded a later blooming plant would not necessarily have more seeds, however, with wider spacing a plant would have more nutrients, etc. available and would benefit with a later blooming date provided the growing season was long enough for the seeds to develop. This caused the discrepancy between this investigation and earlier investigations (Liang 1969, Niehaus and Pickett 1966) where the association between half bloom date and grain yield were positive.

Peduncle diameter, half bloom date, and leaf number show complex interrelationships (Diagram 2). Half bloom date and leaf number are positive and significantly correlated. Sorghum is a species of plant which exhibits terminal inflorescence, or continues to initiate leaves until the panicle is initiated. If floral initiation is delayed, more leaves will be produced. Thus, when half bloom date is lengthened, more leaves will be initiated producing a positive correlation. Peduncle diameter and half bloom date are negatively correlated. With a limited growing season sorghum plants that mature later will not produce peduncles as large as those which undergo floral initiation earlier.

Plant height is positive and significantly correlated to leaf number and to half blooming date. If floral initiation is delayed and more leaves are produced, increased height of the stalk also occurs.

In all investigation except at Powhattan in 1969, leaf area was positive and significantly correlated with half bloom date. This indicates that later blooming varieties have larger leaf areas. However, the association between leaf area and leaf number was highly variable which indicates that leaf number and leaf area appear to develop by separate functions and do not interact significantly.

Stomate number per plant was variable throughout these investigations and was positive and significantly correlated only with leaf number and leaf area. It was associated with plant height but only significant in 2 of the 8 investigations.

The associations determined by this investigation were found using specifically the 36 F_1 hybrids named elsewhere in this paper. Within this group of grain sorghum hybrids the maturity dates varied from early to late maturing ones which did not have a long enough growing season to fully mature at the locations used in this investigation. This along with other factors make the associations determined in this investigation true only for the collective 36 F_1 hybrids used and not necessarily for different years or locations.

Diagram 2. Interrelationships among agronomic traits of grain sorghum, found in this investigation.

⊖ - negative correlation

* - significant

SUMMARY AND CONCLUSIONS

Thirty-six F_1 hybrids were randomly selected and planted at 2 different locations, for two consecutive years (1969 and 1970), and under 2 different plant spacings, 6 and 12 inches, respectively.

Studies were conducted on the interrelationships of 10 agronomic traits. Simple correlation coefficients were obtained in order to estimate the interrelationships of all pairs of traits in this study. Multiple regression and standard partial regression coefficient analysis were made to determine the relationship and relative importance among yield components to grain yield.

Grain yield showed a significant positive correlation with kernel number. Kernel weight was significantly correlated in some replications but not in all of the replications. Half bloom date was significantly negatively correlated with grain yield at the 12 inch spacing both years and locations but not at the 6 inch spacing. Grain yield with head number was variable and tended to be positive, in all of the experiments. Peduncle diameter was highly correlated with grain yield at Powhattan in 1969 but not at Manhattan. In this case a genetic-environment interaction could have taken place. The last half of the growing season was dry and kept grain yield lower and allowed a significant correlation to take place in 1969. There were no other high correlations between grain yield and other agronomic traits studied.

Negative significant correlations were found between kernel number and kernel weight. These correlation coefficients varied from highly negative to not quite significant. At Powhattan in 1970, kernel weight was found to be positively correlated with kernel number. This deviation from the other three interaction outcomes could be due to a climatic interaction with the developmental sequence of the sorghum hybrids.

Interrelationships found in this investigation included: half bloom date was positively correlated with leaf number, plant height, and leaf area; peduncle diameter was negatively correlated with half bloom date and leaf number; half bloom date was negatively correlated with kernel number and kernel weight; and plant height was negatively correlated with kernel number. Interrelationships of other agronomic traits were highly variable throughout this investigation. However, leaf area and leaf number was significantly positively correlated with stomate number per plant. This was to be expected because leaf area and leaf number are functions of stomate number determined in this investigation.

R^2 values of grain yield, computed from multiple regression analysis with 9 other traits, were high. With kernel number and kernel weight contributing comparatively more than the rest of agronomic traits included in the investigation. Standard partial regression coefficient of kernel number and kernel weight were high and significant, with kernel number contributing nearly twice that of kernel weight in their relation to grain yield.

ACKNOWLEDGMENTS

The author wishes to express his sincere appreciation to Dr. G. H. L. Liang for his guidance, advice, and encouragement during the course of this investigation and his assistance in the preparation of this thesis.

Appreciation is expressed to Dr. A. J. Casady, Professor of Agronomy; and Dr. A. D. Dayton, Associate Professor of Statistics, for their advice, review of the manuscript, and helpful criticism during the preparation of this thesis.

The author wishes to express his sincere appreciation and gratitude to his wife, Linda Lee, for her patience, understanding, and support during his course work and preparation of this thesis. Without her assistance and encouragement this study would hardly have been completed.

STOMATA NUMBER AND INTERRELATIONSHIPS AMONG AGRONOMIC
TRAITS IN F₁ HYBRIDS OF GRAIN SORGHUM,
SORGHUM BICOLOR, (L.) Moench

by

CHARLES JOSEPH KNOBLAUCH

B. S., Michigan State University, 1969

AN ABSTRACT OF A MASTER'S THESIS

1970

To fully understand yield, a continual investigation and analysis of the genetic, physiologic, and developmental level will have to be undertaken. The interrelationships of yield components and other agronomic traits are of utmost importance to fully understand yield and to be able to make use of these characteristics in a program for high yielding capacity.

This investigation was designed to estimate the interrelationships of grain yield, kernel number, kernel weight, head number, leaf number, half bloom date, peduncle diameter, plant height, leaf area, and stomate number. With special emphasis on the relationships of grain yield and stomate numbers and on kernel number and kernel weight. Association values for these traits were computed by three methods: simple correlation coefficients for interrelationships, and multiple and standard partial regression analysis for determining the relationships and relative importance among yield components contributing to grain yield.

The experimental materials utilized in this study consisted of 36 F_1 hybrids of grain sorghum. These were planted at 2 locations, for 2 years, with 2 replications, and at 2 different plant spacings, 6 and 12 inches, respectively.

Grain yield exhibited significant positive correlations with kernel number both years and both plant spacings in both locations. Associations of grain yield with kernel weight, plant height, peduncle diameter, half bloom date, and leaf area were variable among plant spacings and locations. These differences could be due to genetic-environmental interactions. The correlation between stomate number and grain yield was very low and nonsignificant, indicating that there is no association or the design was not sensitive enough to detect a significant correlation.

Negative significant correlations were found between kernel number and kernel weight in 3 of the 4 investigations carried out in this experiment. The positive significant correlation at Powhattan in 1970 could have been caused by climatic conditions; temperature, subsoil moisture, specific dates of rainfall, all interacting with the developmental sequence of the sorghum hybrids.

Interrelationships among the agronomic traits were variable with correlations between half bloom date and leaf number, head number and grain yield, peduncle diameter and leaf number (negative), half bloom date and plant height, and leaf number and plant height being the most highly correlated, but not significantly in all cases.

R^2 values of grain yield, computed from multiple regression analysis with 9 other traits, kernel number, kernel weight, head number, leaf number, leaf area, half bloom date, peduncle diameter, plant height, and stomate numbers, were high. Kernel number and kernel weight contributed the most. Standard partial regression coefficients of kernel number and kernel weight were high and significant, with kernel number contributing nearly twice that of kernel weight in their relation to grain yield.
